## 3D ANGIOGRAPHIC ATLAS OF NEUROVASCULAR ANATOMY AND PATHOLOGY

The *3D Angiographic Atlas of Neurovascular Anatomy and Pathology* is the first atlas to present neurovascular information and images based on catheter three-dimensional (3D) rotational angiographic studies. The images in this book are the culmination of work done by Neil M. Borden over several years using one of the first 3D neurovascular angiographic suites in the United States. With the aid of this revolutionary technology, Dr. Borden has performed numerous diagnostic neurovascular angiographic studies as well as endovascular neurosurgical procedures. The spectacular 3D images he obtained are extensively labeled and juxtaposed with conventional 2D angiograms for orientation and comparison. Anatomical color drawings and concise descriptions of the major intracranial vascular territories further enhance understanding of the complex cerebral vasculature.

Neil M. Borden, MD, is a board-certified neuroradiologist who has been practicing for 20 years. He completed a neuroradiology fellowship at the Neurological Institute of New York at Columbia Presbyterian Medical Center and a two-year fellowship in endovascular neurosurgery at the Barrow Neurological Institute in Phoenix, Arizona. Dr. Borden is a senior member of the American Society of Neuroradiology and is currently practicing at the Cleveland Clinic Foundation in Cleveland, Ohio.

## FOREWORD

We have all – patients and physicians alike – come to take the capabilities of diagnostic imaging technology for granted; indeed, our expectations of that technology continue to increase – higher resolution, faster acquisition times, less artifact – the list of demands goes on and on. However, it is scarcely within the span of a generation that lesions considered occult in one imaging modality can now be diagnosed based on features that are pathognomonic in another modality. Young clinicians embarking on their careers at this time may be unaware, for example, that cerebral cavernous malformations with their distinctive appearance on magnetic resonance images were not that long ago considered to be angiographically occult arteriovenous malformations.

I offer this brief historical detail because readers of this volume are about to embark on an amazing three-dimensional visual journey of the circulation of the brain and neck that very few years ago would have been impossible. From the perspective of a neurosurgeon, the appreciation of the vascular system afforded by these images is priceless. Not only does three-dimensional rotational angiography improve the accuracy of diagnosis, it considerably enhances our ability to optimize treatment for patients with challenging neurovascular disorders. Preoperative planning is immeasurably improved by the ability to rotate these images in space to view the posterior regions of vessels that can even be difficult to view intraoperatively. The neck of an aneurysm, for example, can be assessed to determine its suitability for clipping or the presence of other vessels whose inclusion in a clip could be catastrophic. The experience is the neurosurgical equivalent of viewing the dark side of the moon – and always somewhat miraculous to those of us who trained when little more than conventional radiography and angiography were available. To note merely that patient outcomes are concomitantly improved is an understatement that fails to do justice to the lives that can be saved and the devastating complications that can be avoided.

The technology and images showcased in this volume also offer a huge educational benefit. Students, neurosurgical trainees in particular, have always had to struggle with translating the two-dimensional images of neurovascular anatomy in textbooks into the pulsating three-dimensional wonder of the human brain. The hundreds of beautiful images in this text will offer great solace to those striving to master this complex task. The color anatomical illustrations in Chapter 2 and the three-dimensional reconstructions in the orientation insets on each page help readers to place the three-dimensional angiographic images of the vasculature in their anatomical context. The liberal use of conventional angiographic images also helps readers to appreciate the normal anatomy and its perturbation by pathology.

That this superb angiographic atlas was assembled by Dr. Neil Borden is no surprise. Even as a resident Neil gained the reputation of being a “walking radiology encyclopedia” and a “sponge” for knowledge. Between 1994 and 1996, Neil completed a fellowship in interventional neuroradiology with us at the Barrow Neurological Institute in Phoenix. He joined us as a seasoned neuroradiologist who left an established practice to pursue additional training, and I believe that his choice to do so reflects his undiminished love of learning and teaching.

Remarkably, Neil had little experience in research or publishing when he joined us. His commitment and dedication to medical education are now manifest in the volume before you. Having assembled a few neurosurgical atlases during my career, I can assure readers that the finished product is the culmination of hundreds and hundreds of hours spent acquiring and weeding through countless images to optimize the learning process. The technology provides the images, it is true. However, only Neil’s keen intellectual competency could have created this thoughtfully formatted and beautiful atlas. It is my pleasure and honor to recommend *3D Angiographic Atlas of Neurovascular Anatomy and Pathology* to both students and masters of the neurosciences.

---

## INTRODUCTION

Over the last 8 years I have been archiving and cataloging angiographic images that I obtained using one of the first three-dimensional rotational angiographic systems. My career has allowed me to use angiographic cut film, two-dimensional digital subtraction angiography (2D DSA), and now three-dimensional rotational angiography (3DRA). This revolutionary angiographic technique maximizes diagnostic accuracy and provides an invaluable teaching tool for anyone interested in learning more about cerebral vascular anatomy.

The 3D representation of the human neurovascular system represents an enormous step forward in our ability to display this complex anatomy. Our goal in anatomical imaging is to try to recreate the *in vivo* status as close to its natural state as possible.

Until recently we have had to rely solely on 2D representation of this anatomy. Only recently have certain techniques emerged that can display the natural anatomic state in a 3D display. These techniques include 3D rotational catheter angiography, CT angiography (CTA), and magnetic resonance angiography.

There are three reasons why it is important to have the ability to view vascular anatomy in a 3D display. First, a 3D display is a more accurate representation of the pre-existing anatomy of the subject and can only improve our diagnostic accuracy. The evolution of imaging techniques over the last few decades has been aimed at achieving the most accurate reproduction of the anatomy and pathology possible.

The second reason for the importance of 3D display is a natural extension of the first reason. Only through analysis of the true/real anatomic composition of our subject can we make the most appropriate recommendations regarding prognosis and potential interventions (conservative management, traditional surgery, and/or endovascular surgery).

Any technique that converts and illustrates a 3D object as a 2D representation must involve the loss of certain data that can limit the

accuracy of this transformation. This limitation in the representation of vascular anatomy can result in diagnostic inaccuracies and errors in interpretation that can ultimately lead to errors of judgment in therapeutic decisions. Ultimately, patient care can be negatively impacted by traditional 2D imaging methods that do not provide a 3D display of the anatomy.

The third advantage of displaying anatomy in a 3D format involves the education of individuals interested in learning this complex anatomy. This is of great importance to the authors of this book.

Excellent edge resolution can be achieved with both cut film and 2D DSA. However, these techniques lack the ability to provide critical information regarding the dimension of depth. Why is the ability to render depth so important? The cerebral vascular tree is tortuous and inconstant. Vessels often overlap each other. The relationship of one vessel to another provides critical data for operative/endovascular planning and execution.

3DRA has become a valuable tool in assessing the morphology of intracranial aneurysms. The neck of an aneurysm can be more precisely assessed with this technique. In addition, the takeoff of vascular branches and their relationship to the neck and walls of the aneurysm are data that can mean the difference between an easily treatable aneurysm to one that carries a higher risk for the patient. This information is important to have prior to any intervention.

3DRA is unlike any other technique because it allows for an unobtrusive view of the posterior wall of the vessel. This ability improves diagnostic accuracy and ultimately will improve patient care. Pathology does not limit itself to the anterior or lateral regions of a blood vessel. It is the angiographic technique (prior to 3DRA) which has limited assessment of posterior wall abnormalities. With certain steep oblique radiographic projections it might be possible to see certain regions of the posterior/postero-lateral walls of the vessel with high-resolution DSA. In most cases, optimum assessment of the posterior regions is not achievable. This region is easily assessed with 3DRA. In most cases, even direct observation during operative procedures does not allow adequate visualization of the cerebral vasculature.

Interventional neuroradiology has advanced rapidly in a short time. Microcatheter technology allows us to navigate throughout much of the cerebral vascular tree. Vessel relationships and morphologic detail provided by 3DRA can be critical information to those entering the complexity of the human cerebral vascular system. This knowledge can make these procedures safer for the patient.

This technique also enhances preoperative surgical planning. In my practice, the vascular neurosurgeon investigates the 3D image with me in real time at a computer workstation prior to taking patients to the operating room. The ability to observe the vessels in 3D prior to an operative intervention reduces any unwanted surprises at the time of surgery.

One of the limitations of 3DRA is its inability to demonstrate the smaller branches of the vascular tree. The larger proximal vascular trunks and medium-sized vessels are routinely observed and included when possible in this atlas. In my practice, 3DRA has been primarily used in the assessment of the arterial circulation with the only exception being lesions with arterial-venous shunts. Routine utilization of this technique for examining the venous circulation has not been performed except in unusual cases. Another limitation of 3DRA is the lack of visibility of background anatomy that provide spatial references.

This atlas contains images that demonstrate both normal vascular anatomy as well as different pathological entities. The text describes in broad strokes the most commonly encountered patterns of the arterial vascular tree both in the neck and intracranially. We cover the most frequently encountered vessels but leave detailed discussions of the different variations and functional neuroanatomical considerations to other textbooks in this field. We also touch on the subject of the intracranial venous system in more limited fashion as we have used 3DRA only in rare instances to image the venous circulation. 3D examples are supplemented with 2D images where appropriate to further enhance the utility of the atlas.

This book is intended to be a reference atlas of neurovascular anatomy (cervical and intracranial) and pathology. It is not intended to be a primer on the technique of generating 3D images. We have

written this atlas with the intention of enhancing your ability to understand complex neurovascular anatomy. It is our expectation that the knowledge you take from this work will aid in your understanding of neurovascular anatomy in whatever imaging modality or clinical application you choose.

CHAPTER ONE

---

TECHNIQUE OF  
THREE-DIMENSIONAL (3D)  
ROTATIONAL  
ANGIOGRAPHY

---

Angiography is the study of blood vessels. Conventional catheter angiography is a technique that involves the injection of a positive contrast agent directly into the blood vessels through an indwelling vascular catheter (long thin hollow tube). These catheters are generally inserted percutaneously (via needles inserted through the skin).

Cerebral angiography using catheter technology involves accessing the arterial tree most often from the femoral artery (groin). Occasionally the brachial or axillary arteries may be used as the access point.

After the catheter is inserted into the desired arterial access point it is navigated into the vascular territory of interest. In cerebral angiography the catheters are most often placed into the cervical (neck) common carotid artery, internal carotid artery, external carotid artery, or vertebral artery. When nonselective injections are desired the catheters may be positioned in the innominate artery, subclavian artery, or even the aortic arch.

Once the catheter is in the desired position, a bolus injection of a positive contrast agent is performed during which X-rays are obtained for varying periods of time. This allows one to obtain images of the contrast agent as it progresses through the vascular tree from artery to capillary and then into the venous phase of circulation. Most often, the X-rays are obtained in fixed position. Different views of the blood vessels of interest can be obtained either by moving the patient relative to the X-ray tube or changing the position of the X-ray tube relative to a stationary subject. This is the basis for two-dimensional (2D) angiography.

The technique of three-dimensional rotational angiography (3DRA) occurs during the bolus injection of the positive contrast into the vascular tree when a movable X-ray tube rotates in an arc around the patient during acquisition of the X-rays. The X-ray data obtained from this series of exposures is sent to a computer workstation which then creates a 3D model of the vessels studied. This 3D model can then be manipulated

on the workstation in real-time to provide an infinite number of projections (views) of the vessels imaged.

The technique of 3DRA will vary depending upon the manufacturer of the X-ray hardware and software. The author's experience, and all of the 3D images included in this atlas, were acquired using General Electric (GE) LCN+ equipment with a Sun workstation.

The X-ray c-arm (floor mounted X-ray tube and image intensifier) rotates in an arc of approximately 220 degrees around the patient during the injection of a contrast agent bolus. The speed of rotation of the GE equipment was 40 degrees per second. The entire arc of rotation during which data acquisition occurred would take approximately 5 seconds. It acquires approximately 8.8 frames (X-rays) per second generating approximately 44 images in a  $512 \times 512$  matrix over that 5-second timeframe.

During setup for the 3D data acquisition, the region of interest would be placed in the isocenter of the image under fluoroscopy. The blood vessels of interest need to be in the center of the X-ray image in the frontal (AP) and lateral (from the side) projections. This would ensure that X-ray data from all projections would be included in the final 3D model that is generated. If the region of interest were to be placed at the edge of the X-ray field and was not included in the entire rotation, then the final 3D image would not include this partially imaged segment.

The next step after placing the subject in the center of the X-ray image would be to perform a test rotation. This is critical to ensure that there would be no physical collisions between the large, rotating c-arm and any nearby structures. This is especially important when dealing with interventional neuroradiology procedures requiring anesthesia equipment, arterial and other lines, ventilator equipment, and sometimes a ventricular drainage catheter setup. If a test rotation is not done then inadvertent removal of life supporting lines and equipment might occur if there was a collision or if one of the lines were to become tangled with the rotating c-arm gantry.

The technique of 3DRA utilizes a single bolus injection of contrast. As opposed to standard 2D angiography where the contrast bolus is visualized as it progresses through the vascular tree, the goal of imaging with 3DRA is to obtain all of the X-ray images in the same phase of circula-

tion. Most often the arterial phase is desired, although this can be altered so that the venous phase can be the predominant portion of the vascular bed imaged. Since the image data is acquired over a 5-second time period during the arc of rotation, the goal of the injection is to opacify the desired vessels during the entire 5 seconds. Through experience we found that in most cases adequate opacification could be accomplished with approximately 15 cc total volume injected at a rate of 3 cc per second. These numbers could be modified depending on the size of the vessel where the catheter was residing, the cardiac output, and whether we were trying to image a high-flow state such as an arterial-venous malformation (AVM). We did not have a single complication related to these injection volumes over a 4-year period.

The operator/physician chooses a delay time to begin the rotational sequence after initiating the contrast injection. When the arterial circulation is the desired phase of circulation to be imaged, the delay is usually between 0.5 and 2 seconds depending upon the position of the catheter tip relative to the vessels of interest and the patient's cardiac output. The closer the catheter tip is to the area of interest the shorter the needed delay. When patients have impaired cardiac function, a longer time delay may be required to allow time for the injected contrast to reach the area of interest. Again, the goal is complete opacification of the vasculature of interest for the entire rotational sequence (about 5 seconds). Occasionally, when the venous circulation is the region of interest, much longer delay times are used. This can be estimated by evaluating the timing of the appearance of the veins on prior 2D angiographic sequences.

Once the rotational sequence is completed, the data is transferred to the Sun workstation where a 3D model is generated. With a 3D model available the operator/physician applies a threshold and utilizes other 3D tools to generate the final 3D image.

A variety of reconstruction algorithms are available which include shaded surface display (SSD), maximum intensity projection (MIP), volume rendering (VR), and a navigator view which allows for an endoluminal view of the vessels in the 3D volume set.

Most of the 3D images in this atlas are shaded surface display 3D images. This algorithm simulates a light source projected on the model, which generates varying shades of gray that enhance the 3D perspective.

After several software updates, a program was developed which allowed reconstruction of surgical clips and endovascular coils in the 3D image. When possible, I include some of these images in the atlas.

As stated in the “Introduction”, there are certain limitations inherent with 3DRA technique. Visualization of small/distal vessels is limited. This limitation is partly related to the lower injection rate used compared with standard two-dimensional digital subtraction angiography (2D DSA). A second limitation is the lack of bony landmarks on the final 3D image. A third limitation is the lack of sequential visualization of angiographic images showing the progression of contrast through the various phases of circulation. For this reason 3DRA should not replace traditional high resolution 2D DSA, but should complement the angiographic examination.

CHAPTER TWO

---

COLOR ILLUSTRATIONS  
OF NORMAL  
NEUROVASCULAR  
ANATOMY

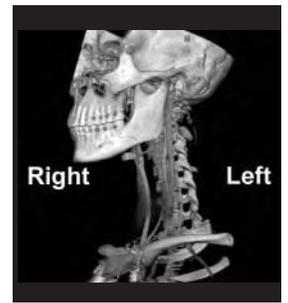

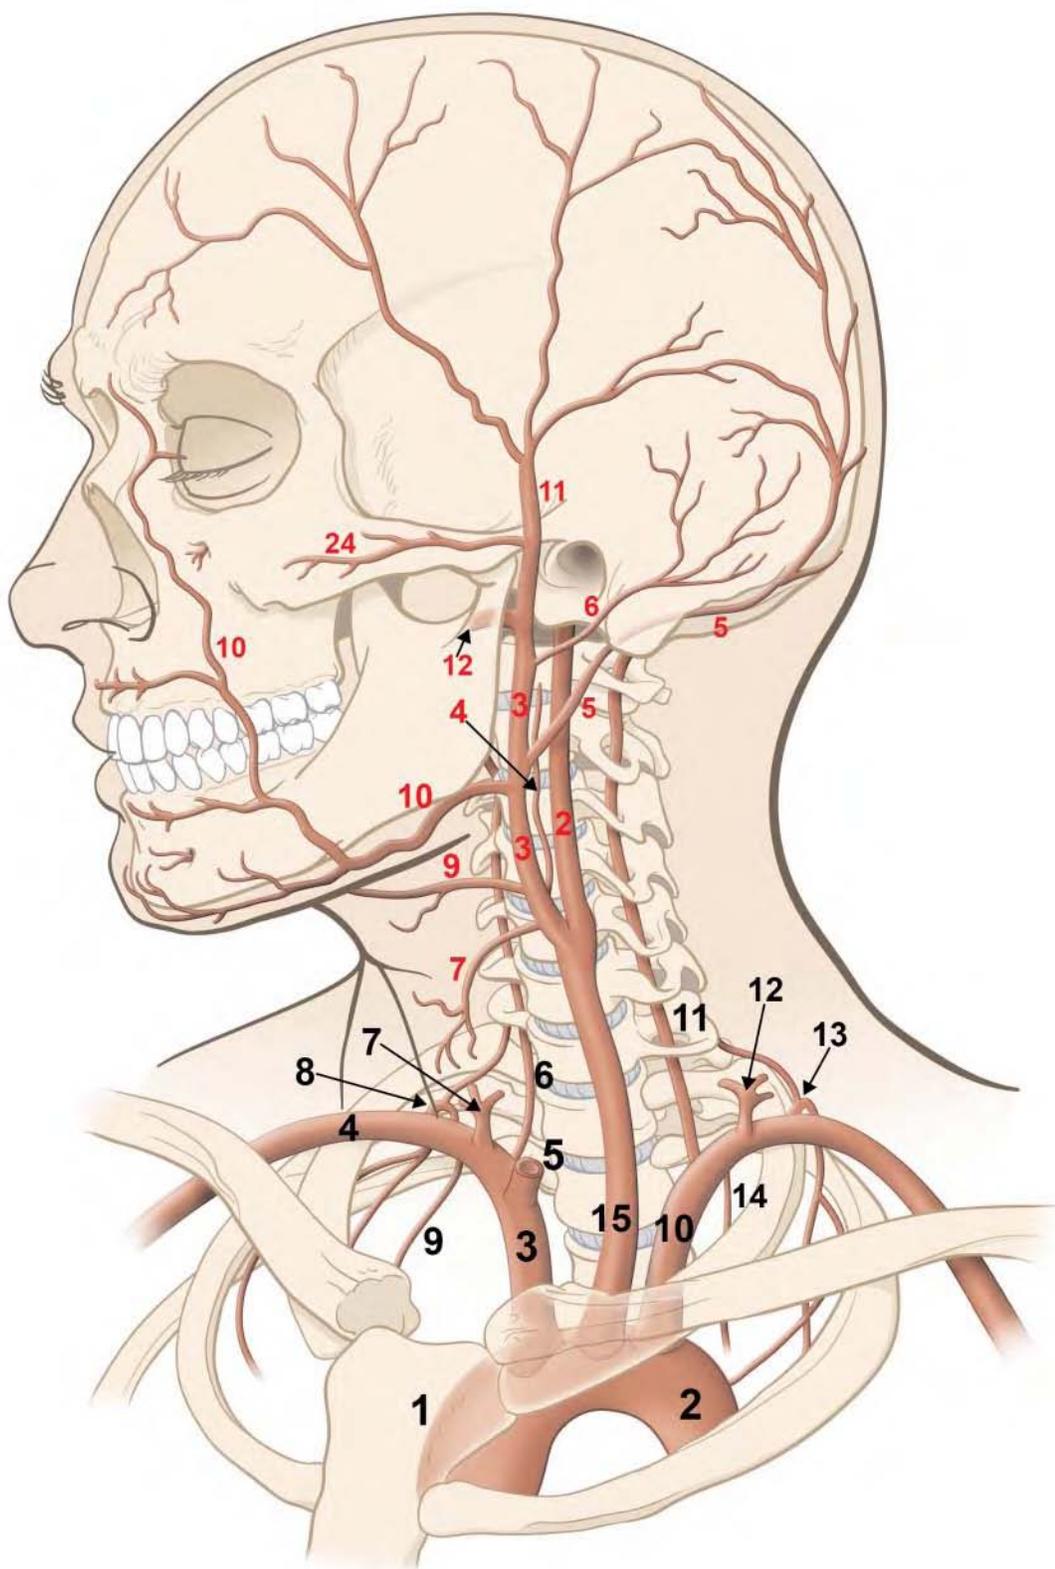

---

The illustrations in this chapter are intended to provide the reader with a reference point for the images that follow in subsequent chapters. These illustrations provide the reader with the necessary background anatomy and the most commonly encountered patterns of vascular branching.

Variability and inconstancy are the rule rather than the exception in how the vasculature tree branches within the neck and face, as well as how it branches intracranially. It is important to understand that vessels are named for the territory of tissue that they supply. We hope that your understanding of neurovascular anatomy is enhanced by the application of this concept in the atlas.

The illustrations that are presented are meant to provide the reader with a basic understanding of the relationship of the vascular tree with the tissues they nourish. During your journey through this three-dimensional (3D) atlas, refer back to these color illustrations when needed.

CHAPTER THREE

---

THE AORTIC ARCH

---

The aortic arch is the main conduit through which arterial blood pumped from the left ventricle of the heart is transmitted to the entire body. Blood passes through the aortic valve and enters the ascending thoracic aorta. This is a tubular structure, 4 to 5 cm in length, and usually of uniform caliber. The ascending aorta is continuous with the aortic arch at about the right second costal cartilage. Blood is then directed into the upper extremities and the head and neck through the innominate artery, the left common carotid artery, and the left subclavian artery. These vessels are collectively referred to as the great vessels. They arise in that order (in most instances) from the aortic arch. The aortic arch is semicircle in shape. Beyond the takeoff of the great vessels, the diameter of the aortic arch is approximately two-thirds that of the ascending aorta (1).

In a typical situation, the first branch of the aortic arch is the innominate artery. This vascular pedicle ascends toward the right and divides into the right common carotid artery and the right subclavian artery.

The innominate artery continues beyond the takeoff of the right common carotid artery as the right subclavian artery. Arising from the superior aspect of the right subclavian artery (in order) are the right vertebral artery, the right thyrocervical trunk, and the right costocervical trunk. The right internal mammary artery arises from the inferior aspect of the right subclavian artery usually opposite that of the right vertebral artery. The right vertebral artery courses superiorly and medially to enter the foramen transversarium of the cervical spine. Ninety-five percent of the time the artery then enters C6. In 5 percent of the cases, the artery enters a foramen transversarium at another variable level (2). Blood flowing through the right subclavian artery will eventually supply the right upper extremity more distally.

Beyond the innominate artery the next branch that is usually encountered is the left common carotid artery. In the majority of cases, the

common carotid artery arises from the aortic arch or the innominate artery. Seventy-five percent of the time it arises from the aortic arch (2). It is also not unusual that it arises in common origin with the innominate artery. It also may arise from the medial aspect of the innominate artery. This anatomic relationship can result in a technically more difficult catheterization.

The last branch and the most left-sided of the branches to arise from the aortic arch is the left subclavian artery. Typically, the first branch of the left subclavian artery is the left vertebral artery. In a similar fashion as the right side, it courses superiorly and medially towards the cervical spine. In 95 percent of the instances it ascends in the neck after entering the foramen transversarium of C6. Five percent of the time it enters the foramen transversarium at other variable levels (2). The left thyrocervical and costocervical trunks arise from the superior aspect of the left subclavian artery beyond the left vertebral artery. The internal mammary artery arises from the inferior aspect of the subclavian artery opposite the vertebral artery. In approximately 6 percent of the cases, the left vertebral artery arises directly from the aortic arch between the left common carotid artery and the left subclavian artery. When this happens the left vertebral artery will usually enter the foramen transversarium at C4 or C5 (2). As on the right side, blood flow through the left subclavian artery will eventually supply the left upper extremity more distally.

There are numerous congenital anomalies and developmental variations in the anatomy of the aortic arch and the branching of the great vessels. These are beyond the scope of this atlas.

There are factors that limit the utility of three-dimensional rotational angiography (3DRA) in the imaging of the aortic arch. In order to achieve adequate opacification of the aortic arch and its vessels, an unacceptably large volume of contrast would have to be injected. In addition to this, the degree of cardiac/aortic pulsation during the 5-second injection and the acquisition of the 3DRA would create a large amount of motion artifact that would degrade the diagnostic quality of the angiographic images. Despite these limitations a few 3D angiograms of the aortic arch were obtained during early experiences with this technique. In certain limited indications, the 3DRA technique was also utilized in the assessment of the great vessels.

CHAPTER FOUR

---

CERVICAL  
VASCULATURE

---

## I. CAROTID CIRCULATION

The common carotid arteries ascend within both sides of the neck. They are invested by a condensation of the deep layer of the cervical fascia (carotid sheath) along with the internal jugular vein and vagus nerve (cranial nerve X). The carotid sheath structures are deep to the sternocleidomastoid muscle. The common carotid artery (CCA) lies medial to the internal jugular vein. At the C3-4 (34 %) or C4-5 (46 %) level the common carotid artery bifurcates into the external carotid artery (ECA) and the internal carotid artery (ICA) (1). The bifurcation can occur as high as C1 or as low as T2 (2). The proximal internal carotid artery most often lies postero-lateral to the proximal external carotid artery and medial to the internal jugular vein. The internal carotid artery ascends almost vertically in the neck and enters the skull base through an aperture within the petrous bone called the carotid canal. There are no major named branches of the ICA within the neck. Rarely one may encounter takeoff of an occipital or other normal branch of the ECA from an otherwise normal ICA.

After arising from the common carotid artery, the external carotid artery travels in a tortuous course within the deep spaces of the upper neck/face and gives rise to multiple branches that supply the face, scalp, major portions of the dura, and upper pole of the thyroid gland. These include the superior thyroid artery, ascending pharyngeal artery, lingual and facial arteries, occipital artery, posterior auricular and muscular branches that supply the masseter, the buccinator, and the pterygoid muscles. The two terminal branches of the primary external carotid artery are the superficial temporal artery (STA) and the internal maxillary artery (IMAX). These terminal branches arise near the superior ramus of the mandible. The STA arises within the parotid gland ascending deep to the temporalis muscle, crosses the zygomatic process giving off the transverse facial artery, and divides into terminal branches to supply the majority of the

scalp. The IMAX is typically the largest terminal branch of the ECA originating behind the neck of the mandible coursing medially towards the sphenopalatine fissure giving off numerous branches along its course. The three portions of the IMAX are the first or mandibular, second or pterygoid, and the third or pterygopalatine.

The mandibular portion arises within the parotid gland and then courses inferiorly along the lateral pterygoid muscle. Its branches are the middle meningeal, accessory meningeal, inferior alveolar, deep auricular, and anterior tympanic arteries. The pterygoid portion courses anteriorly, superiorly, and medially through the infratemporal fossa. Its branches include the buccal, masseteric, and deep temporal arteries. The pterygopalatine portion lies within the pterygopalatine fossa. Its branches are named for the foramen or fissures from which they exit the pterygopalatine fossa including four anterior and three posterior branches. The anterior branches include the posterior superior alveolar, infraorbital, greater (descending) palatine, and sphenopalatine arteries. The posterior branches include the arteries of the foramen rotundum, artery of the pterygoid canal (vidian artery), and the pterygovaginal (pharyngeal) artery which courses through the palatovaginal canal in the skull base (2,3).

The middle meningeal artery is the largest meningeal vessel and the largest branch of the internal maxillary artery (4). It has a short vertical segment then enters the cranium through the foramen spinosum and then abruptly courses ventrally (anteriorly) to run along the dura within the grooves of the inner table of the middle cranial fossa to the internal surface of the frontal and parietal bones. The middle meningeal artery commonly supplies convexity meningiomas. A small petrous branch of the middle meningeal artery can supply the vasa nervorum of the facial nerve (cranial nerve VII) in the middle ear. Facial paralysis, secondary to untoward occlusion, can occur during embolization through the middle meningeal artery if small particles or liquid embolic agents are used. Anastomosis between middle meningeal artery branches and lacrimal branches of the ophthalmic artery may provide collateral blood flow in the setting of internal carotid artery occlusion. This communication is demonstrated in Figures 4.9 and 4.10. This potential communication can also result in blindness during embolization through the middle meningeal artery.

Branches of the pterygopalatine portion of the internal maxillary artery include the infraorbital artery, sphenopalatine artery, and the artery of the foramen rotundum. The infraorbital artery courses through the infraorbital canal and infraorbital foramen supplying the cheek, lower eyelid, upper lip, lacrimal sac, and nose (4). It can also anastomose with terminal branches of the ophthalmic artery as well as provide potential collateral blood flow in the setting of internal carotid artery occlusion.

The sphenopalatine branch of the distal internal maxillary artery supplies the nasal cavity and is often the source of bleeding in posterior epistaxis. Particulate embolization of the distal internal maxillary artery is often directed towards the treatment of posterior epistaxis when bleeding from the sphenopalatine artery is believed to be the source.

Numerous small anastomotic channels exist between branches of the external carotid artery and the intracranial circulation. Branches of the middle meningeal artery, the accessory meningeal artery, and the artery of the foramen rotundum normally anastomose with the inferolateral trunk (artery of the inferior cavernous sinus). These anastomotic channels can provide collateral flow to the horizontal intracavernous segment of the intracranial internal carotid artery (5). They may also provide arterial supply to dural arterial venous fistulas around the cavernous sinus and skull base. In addition these various arterial branches often provide nutrient supply to the vasa nervorum of a number of cranial nerves. Careful attention to the presence of these extracranial to intracranial communications, as well as their importance in the integrity of multiple cranial nerves, is mandatory when embolization procedures are performed in the external carotid artery territory (6).

Another important extracranial to intracranial anastomotic channel is between the occipital artery and the upper cervical vertebral artery. This normal communication is not often readily visible on routine angiographic studies. Extreme caution must be exercised when embolization involving the occipital artery is undertaken to prevent potential inadvertent embolization of the vertebral basilar circulation.

Utilization of three-dimensional rotational angiography (3DRA) has significant benefits compared to traditional 2D-angiography in the evaluation of carotid artery disease in the neck. 3DRA provides an infinite number of

imaging projections of the common carotid artery bifurcation obtained through a single contrast injection. By providing these multiple views we can have confidence in the accuracy of our estimation of the degree of vascular stenosis (narrowing). In addition to enhancing our accuracy in evaluating stenosis, our ability to identify complicated atherosclerotic plaques with ulcerations is enhanced.

The acquisition of infinite projections from a single bolus injection of contrast is also beneficial. This reduces the overall volume of contrast needed to complete the angiographic exam, thereby reducing the potential for harmful effects of the radiographic contrast media.

As a result of the advantages of 3DRA compared with traditional 2D imaging, we have the potential to improve patient care through the more accurate assessment of atherosclerotic vascular changes. This might alter and improve treatment options for these patients.

In contrast to the added benefits of 3DRA in assessing the common carotid artery bifurcation, this technique was found to be of limited benefit in angiographic assessment during selective external carotid angiography for a variety of indications. The factors limiting the use of 3DRA in external carotid angiography include the small size of the various branches of the external carotid artery that limit their opacification, patient movement during these injections (which can be uncomfortable), and the propensity for the branches of the external carotid artery to undergo vasospasm from catheter manipulation.

## II. VERTEBRAL ARTERIES

After arising from the subclavian arteries (or occasionally directly from the aortic arch on the left), initially the vertebral arteries course medially and superiorly and, in most cases, enter the foramen transversarium of C6. They then ascend vertically in the foramen transversaria C6 through C3 turning superolaterally to pass through the foramen transversarium of C2. They remain anterior to the ventral roots of the cervical spinal cord with the exception of the first cervical root where they are lateral to the roots. The vertebral arteries then course superiorly and slightly anteriorly pass-

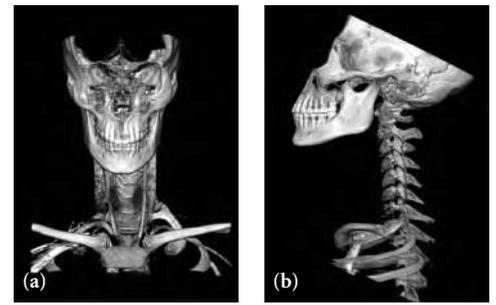

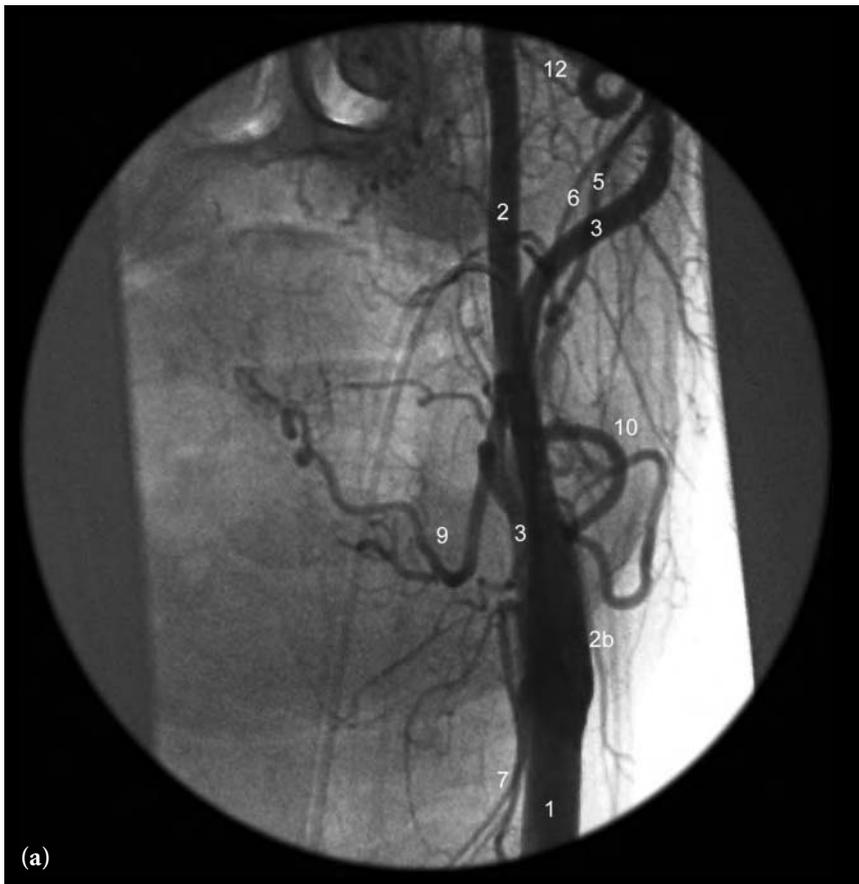

ing through the transverse foramen of the atlas. Near the cranio-vertebral junction, the vertebral arteries course posteriorly around the atlanto-occipital joint (7) and lie over the posterior neural arch of C1. They then make a sharp turn to change their direction superiorly and anteriomedially to enter the cranial cavity through the foramen magnum. They pierce the dura to enter the subarachnoid space just above the bony posterior neural arch of C1. Often a mild change in caliber or mild ring-like constriction of these vessels is seen as they pierce the dura. The vertebral arteries unite to form the basilar artery near the inferior pons/ponto-medullary junction. The vertebral arteries are usually unequal in size. The left vertebral artery is often larger than the right artery. Hypoplasia of a vertebral artery is not unusual.

Within the neck, the vertebral arteries give rise to numerous small deep muscular branches as well as small segmental branches to the bony cervical spine and spinal cord (7). Inconstant, variable vascular supply to the cervical spinal cord via the radiculomedullary branches of the vertebral arteries is noted. Radiculomedullary refers to the segmental nature of the vascular supply to the spinal cord. Often a single dominant arterial branch to the brachial widening (brachial plexus C4-T1) of the cervical spinal cord arises from one or both vertebral arteries. At other times this important branch may arise from the thyrocervical trunk, costocervical trunk, or even from branches of the external carotid artery such as the superior thyroid artery.

CHAPTER FIVE

---

INTRACRANIAL  
CAROTID ARTERY  
CIRCULATION/ANTERIOR  
CIRCULATION

---

The intracranial internal carotid artery (ICA) has petrous, presellar, intracavernous, and supraclinoid segments. In the illustrations and legend keys we further subdivide those segments into the vertical and horizontal petrous, presellar (Fischer C5), horizontal intracavernous (Fischer C4), anterior genu (Fischer C3), as well as the proximal and distal supraclinoid segments. This is the nomenclature we find most helpful in discussing the anatomy and the relevant pathology.

After entering the skull base the internal carotid artery travels within the vertical and horizontal segments of the petrous carotid canal before emerging near the petrous apex. It courses over the foramen lacerum in the distal horizontal segment and then assumes a vertical orientation to become the presellar or Fischer C5 segment. Near the posterior aspect of the sella turcica the ICA changes from a vertical to an anteriorly projecting horizontal path to become the Fischer C4 or horizontal intracavernous segment. The size and extent of the cavernous sinus is variable and therefore the level where the ICA pierces the dura is also variable. For the purposes of this atlas, we will consider that the ICA pierces the dura of the cavernous sinus near the Fischer C5-C4 junction.

The intracavernous ICA gives rise to several small branches. The meningohypophyseal artery (MHA) trunk most often arises from the posterior wall of the ICA at the Fischer C5-C4 junction. This normally small vessel can often be seen on high-resolution two-dimensional digital subtraction angiography (2D DSA). Visualization of the normal-sized proximal MHA trunk with 3DRA occurs to a variable degree. The inferolateral trunk or artery of the inferior cavernous sinus most often arises from the lateral aspect of the Fischer C4 segment. Occasionally seen on routine 2D DSA, this vessel is usually not seen on routine 3DRA unless it is pathologically enlarged. Variably arising medially from the Fischer C4 segment are normally tiny capsular branches (McConnell's capsular arteries). These

branches course medially along the sellar floor in an extradural position. They anastomose with their counterparts on the opposite side.

The intracavernous ICA has a sinuous course from posterior to anterior. The most posterior aspect is usually the most medial segment. We will also call the Fischer C5-C4 junction the first (posterior) genu of the intracavernous ICA. In the anterior cavernous sinus a second (anterior) genu occurs where the ICA becomes the Fischer C3 segment. It turns superiorly and posteriorly as it courses just inferior and medial to the anterior clinoid process. It is still within the cavernous sinus but will soon pierce the dura of the cavernous sinus a second time before it becomes subarachnoid in the supraclinoid segment.

The origin of the ophthalmic artery varies, arising near the junction of the anterior genu and supraclinoid segments. It is typically depicted as the last Fischer C3 vessel (1) and infraclinoid (2,3). The ophthalmic artery most often arises from the medial margin of the paraclinoid segment of the ICA. In approximately 90% of all individuals, the origin of the ophthalmic artery is intradural in location (4). In other words, it most often arises just above where the intracavernous ICA pierces the dura for a second time (the dural ring).

We divide the supraclinoid segment into the proximal and distal supraclinoid segments. The portion between the anterior genu/Fischer C3 segment and the posterior communicating artery (PCoA) will be called the proximal supraclinoid segment and the distal supraclinoid segment will include the PCoA and anterior choroidal artery ending at the ICA bifurcation. We use the terms proximal and distal supraclinoid instead of Fischer C1 and C2 as we find them to be more descriptive, universal, and simplistic.

A very small branch to the pituitary gland arises from the superior-medial margin of the proximal supraclinoid segment of the ICA. This is called the superior hypophyseal artery. This is generally not seen on 3DRA unless pathologically enlarged.

Arising from the posterior wall of the supraclinoid segment of the ICA distal to the superior hypophyseal artery are the PCoA and the anterior choroidal arteries (from inferior to superior). The proximal portion of these vessels is frequently seen on 3DRA. A junctional dilatation or infundibulum is also seen and can be easily differentiated from small aneurysms on 3DRA because of the infinite number of views available.

This, however, can often be a source of diagnostic uncertainty on routine 2D DSA. The ability to differentiate between a nonpathologic infundibulum and an aneurysm on 2D DSA is limited because of the limited number of views this technique offers.

The distal supraclinoid segment of the intracranial ICA beyond the anterior choroidal artery ends at the ICA bifurcation. The two major divisions of the ICA bifurcation are the A1 and M1 segments of the anterior (ACA) and middle cerebral arteries (MCA). The medial and lateral lenticulostriate arteries arise from the A1 and M1 segments, respectively. When these vessels are pathologically enlarged or arise from a larger trunk that subsequently divides into individual perforating arteries the larger proximal trunks are often visualized on 3DRA.

The nature of the intracranial circulation is one of variability and inconsistency. General schemas on the naming of individual intracranial branches are often based on the distal cerebral territory supplied. For instance, one would name a specific branch to the pre-central/pre-rolandic gyrus (motor strip) as the pre-central or pre-rolandic branch. This is a useful scheme as it more clearly defines the parenchymal vascular territory. One can then infer (within certain limitations) the functional importance of a particular vascular branch. To aid in the naming of the cortical branches, Salamon et al. devised a clear plastic disc to be used as a template that could be placed over the lateral carotid angiogram to provide a convenient means to identify the cortical branches (5).

The A1 segment of the ACA extends from the ICA bifurcation to the A1-A2 junction. The A1 segment courses slightly anterior in a medial direction towards the midline. When it reaches the A1-anterior communicating artery (ACoA) junction it changes course. It then runs superiorly as the A2 segment. The first branch of the A2 ACA is the orbitofrontal artery and the second branch is the frontopolar artery. Variable branching of the A2 into the pericallosal and callosomarginal branches follows. The pericallosal artery runs in the pericallosal cistern while the callosomarginal branch runs in the cingulate sulcus, just above the cingulate gyrus. A single pericallosal artery is seen supplying both cerebral hemispheres in 10% of the cases (6). Branches of the pericallosal and callosomarginal arteries divide into the branches that supply the medial surface of the frontal and parietal lobes and the medial one-third of the cerebral hemisphere in the

frontal and parietal regions. The callosomarginal artery is usually the smaller of the two giving rise to the anterior, middle, and posterior internal frontal arteries, usually wandering off the midline. The pericallosal artery gives rise to three major branches: the paracentral, the superior internal parietal (precuneal), and the inferior internal parietal branches. The distal aspect of the callosomarginal artery runs in the callosomarginal fissure which lies just posterior to the mesial continuation of the central sulcus. The distal pericallosal artery courses under the splenium of the corpus callosum into the transverse fissure anastomosing with the splenial or posterior pericallosal artery, a small branch of the posterior cerebral artery. In cases of ACA or PCA occlusion this can provide anastomotic collateral flow to the occluded vascular territory. It is also necessary to discuss the Recurrent Artery of Heubner. This important perforating artery arises most often from the distal A1 or proximal A2 segment. It courses laterally, running parallel to the A1 ACA and M1 MCA axis and then enters the anterior perforated substance to supply the caudate head, lateral putamen, and the anterior limb of the internal capsule.

The M1 segment of the middle cerebral artery courses laterally in the horizontal sylvian cistern. Frequently, an early cortical branch to the anterior temporal lobe arises from the M1 segment of the MCA. This branch courses inferiorly around the tip of the anterior temporal lobe. Coursing laterally within the sylvian fissure, the MCA bifurcates (75%) or trifurcates (25%) (7). There is variability in the location of the middle cerebral artery bifurcation/trifurcation. In the majority of cases the location is where the sylvian fissure changes from a horizontal to an anterior to posterior axis, the genu or knee of the MCA. The MCA branches within the sylvian fissure posterior to the bifurcation/trifurcation overlie the insular cortex. These are referred to as the M2 branches. The different divisions of the middle cerebral artery continue to divide into cortical branches supplying the lateral convexity surfaces of the frontal, temporal, and parietal lobes. The branches coursing over the various opercular are designated as the M3 branches. The distal cortical ramifications of the MCA designated M4 branches supply the lateral two-thirds of the cerebral hemisphere.

The distal cortical branches of the MCA are named for their vascular territories. In the most common branching pattern, an MCA bifurcation, the anterior-superior division gives rise to the orbitofrontal branch sup-

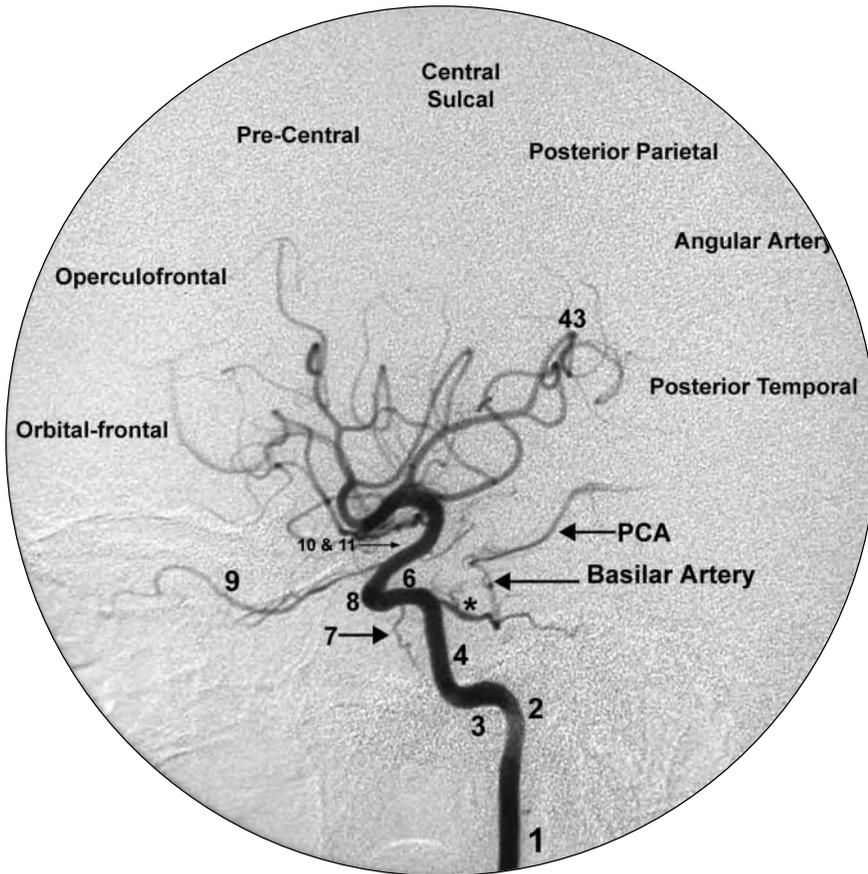

plying the inferolateral frontal lobe and the operculofrontal branches (candelabra group) supplying the middle and inferior frontal gyri including Broca's region. Arising posteriorly to these branches, the pre-central and central rolandic branches ascend to supply the motor and sensory gyri, respectively. The posterior-inferior division of the middle cerebral artery include the anterior and posterior parietal branches supplying the ventral parietal lobe, the angular artery running parallel to the sylvian fissure and then posteriorly and superiorly to supply the inferior parietal lobule, the lateral occipital lobe and the superior temporal lobe, as well as the middle and posterior temporal branches that course laterally around the convexity surface of the temporal lobe to supply the remainder of the temporal lobe.

Mention should also be made of the sylvian point. The sylvian point corresponds to the most superior and the most medial point where the last sylvian MCA branch turns inferolaterally to exit the posterior and superior aspect of the sylvian fissure. In the pre-crosssectional neuroimaging era, when angiography was the usual procedure for diagnosing intracranial lesions, multiple points of reference including the sylvian triangle were necessary tools for diagnosis. The sylvian triangle represents the geometric representation of the middle cerebral arteries overlying the insular cortex. Distortions of this triangle help in the localization of intracranial lesions.

| 21 callosomarginal branch of anterior cerebral artery                    |  |
| 22 orbitofrontal branch of anterior cerebral artery                      |  |

**Fig. 5.3** A 2D frontal view following right common carotid artery injection. This view shows the normal appearance of the intracranial internal carotid artery circulation with filling of the anterior and middle cerebral artery branches. There is filling of both sides from a patent anterior communicating artery. There is also a small clival branch of the meningohypophyseal trunk providing flow to the left intracranial internal carotid artery (4). Note the prominent superimposition of the different ACA and MCA branches on this projection limiting identification of individual named branches.

## FIGURE KEY

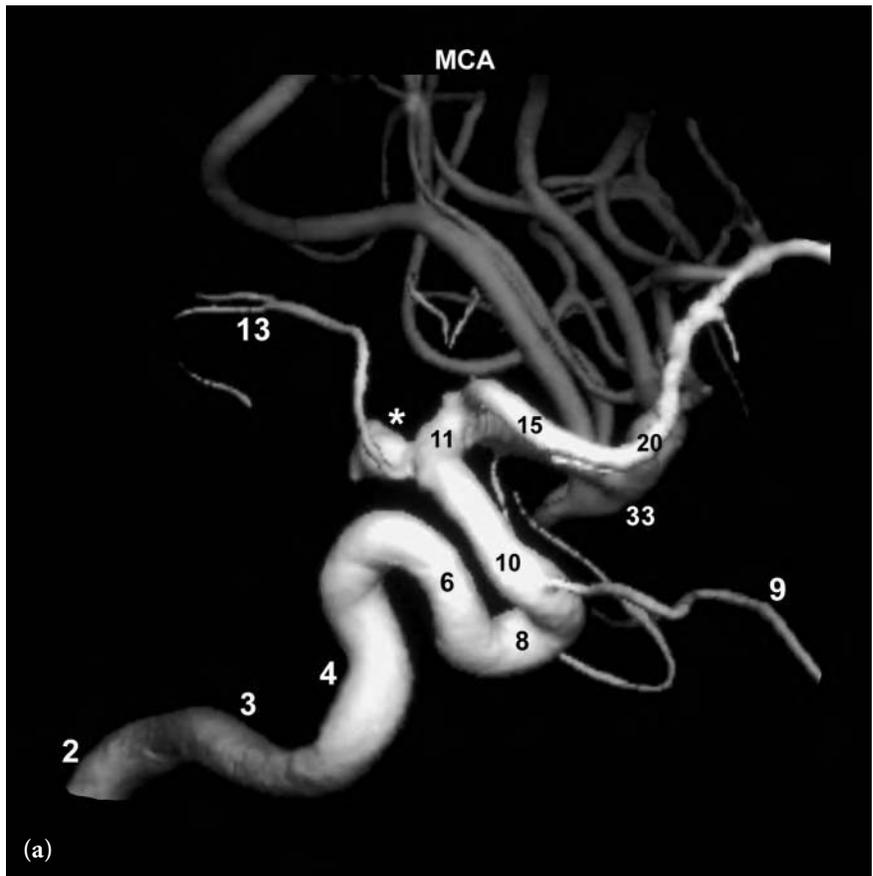

**Fig. 5.16** A 3D posterior view following left internal carotid artery injection. Three separate aneurysms are identified. One aneurysm arises from the posterior wall of the supraclinoid segment of the internal carotid artery at the level of the posterior communicating artery. The second, smaller aneurysm arises from the posterior wall of the supraclinoid internal carotid artery just inferior to the internal carotid artery bifurcation. The third and largest aneurysm arises from the internal carotid artery bifurcation and projects superiorly.

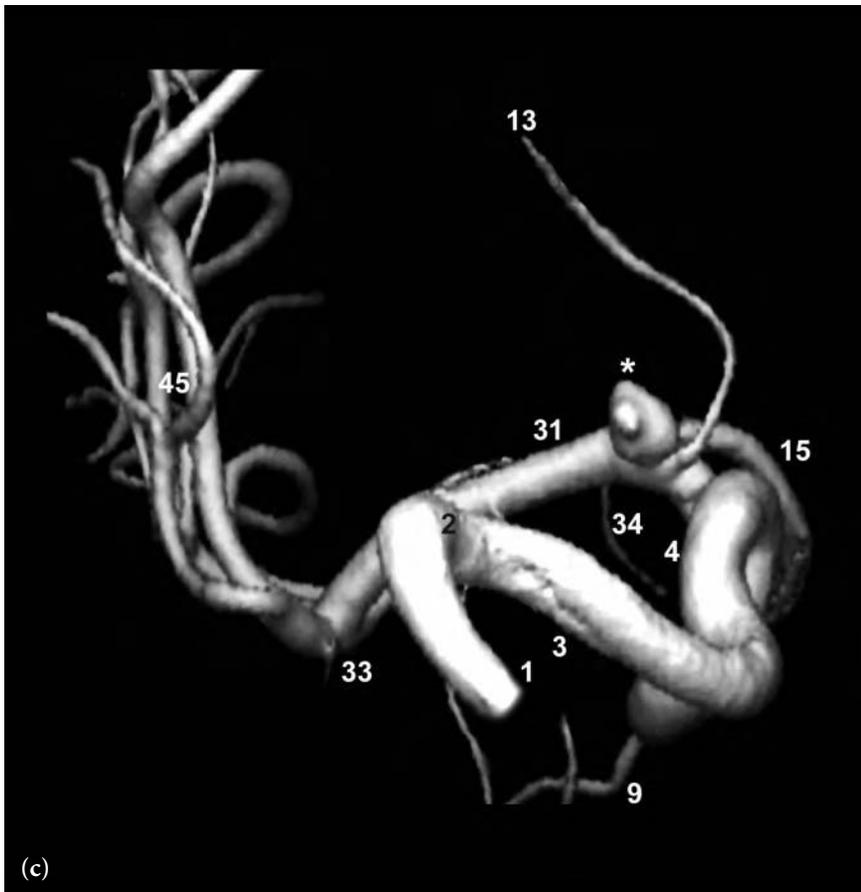

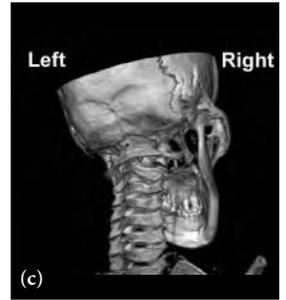

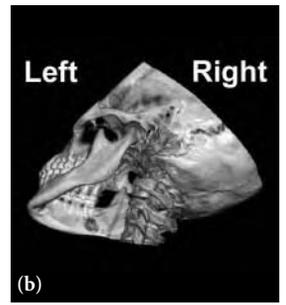

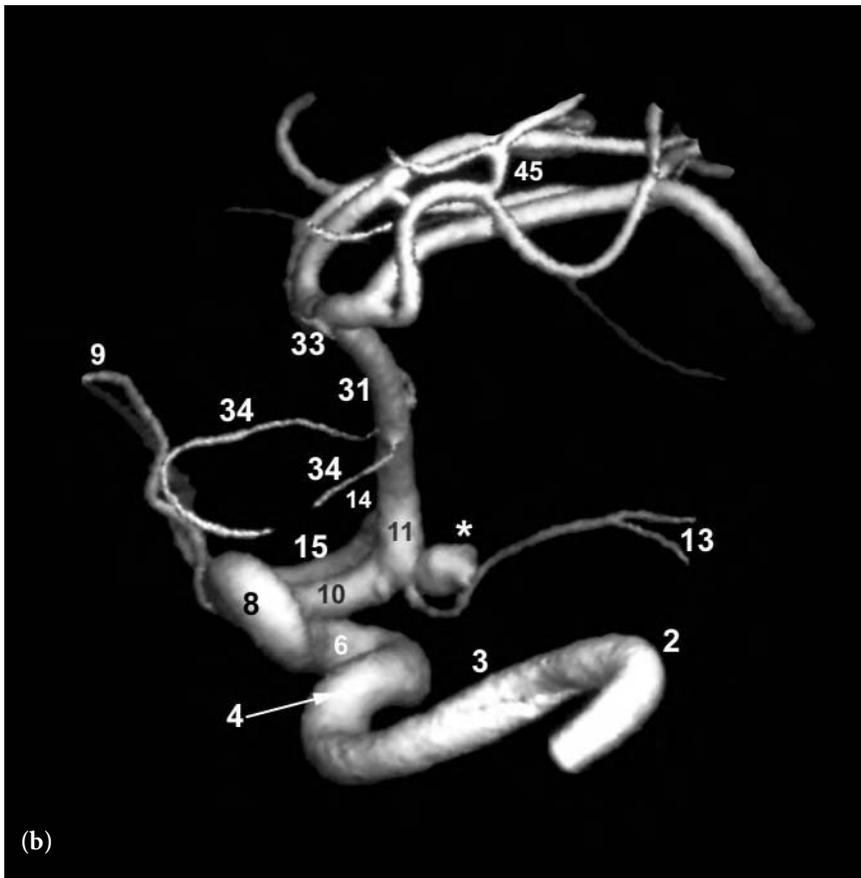

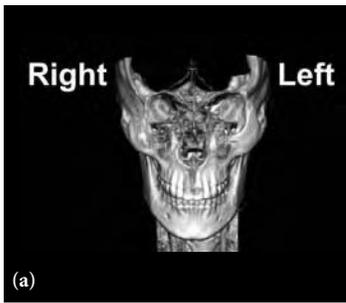

**Fig. 5.17 (a–c)** 3D medial (a), inferior to superior left posterior oblique (LPO) complex angle (b), and inferior to superior right posterior oblique (RPO) (c) views following left internal carotid artery injection. There is an aneurysm rising from the posterior wall of the supraclinoid segment of the internal carotid artery at the takeoff of the anterior choroidal artery. Note the small focal lobulation along the posterior-inferior aspect of the aneurysm in (c) which is a focal area of weakness/thinning of the aneurysm wall and a potential site for rupture.

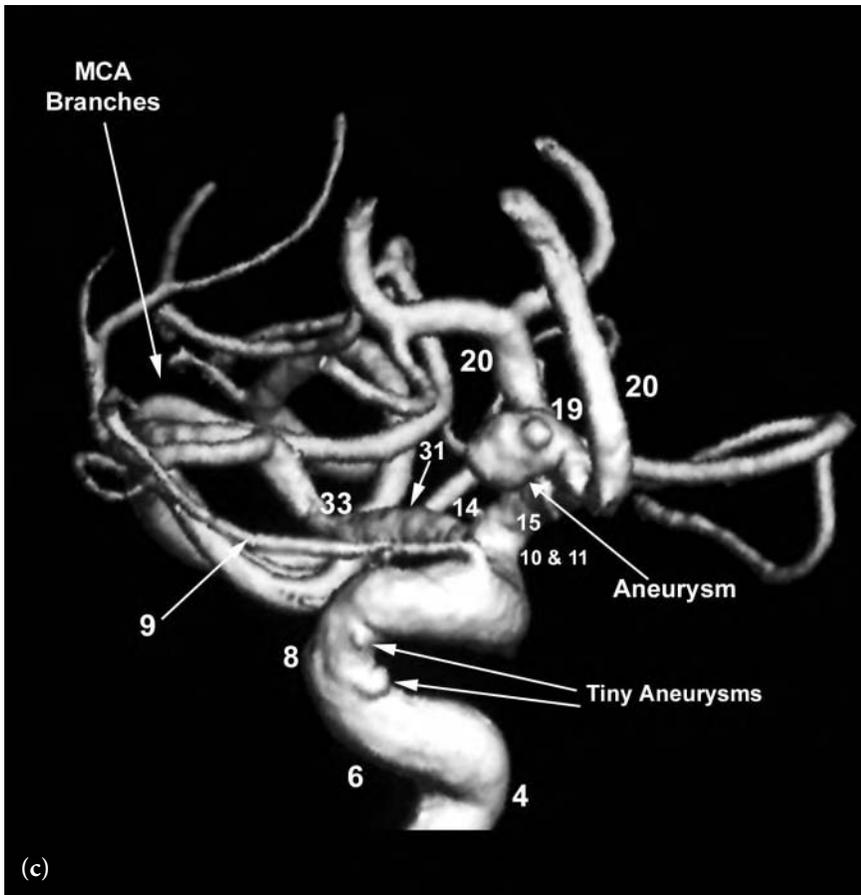

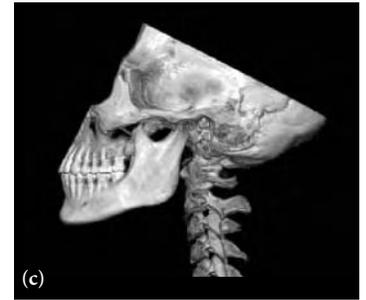

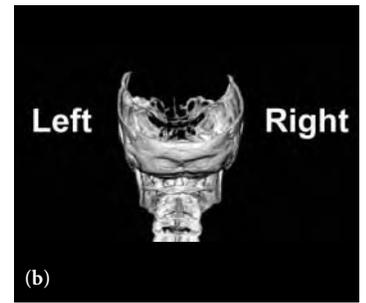

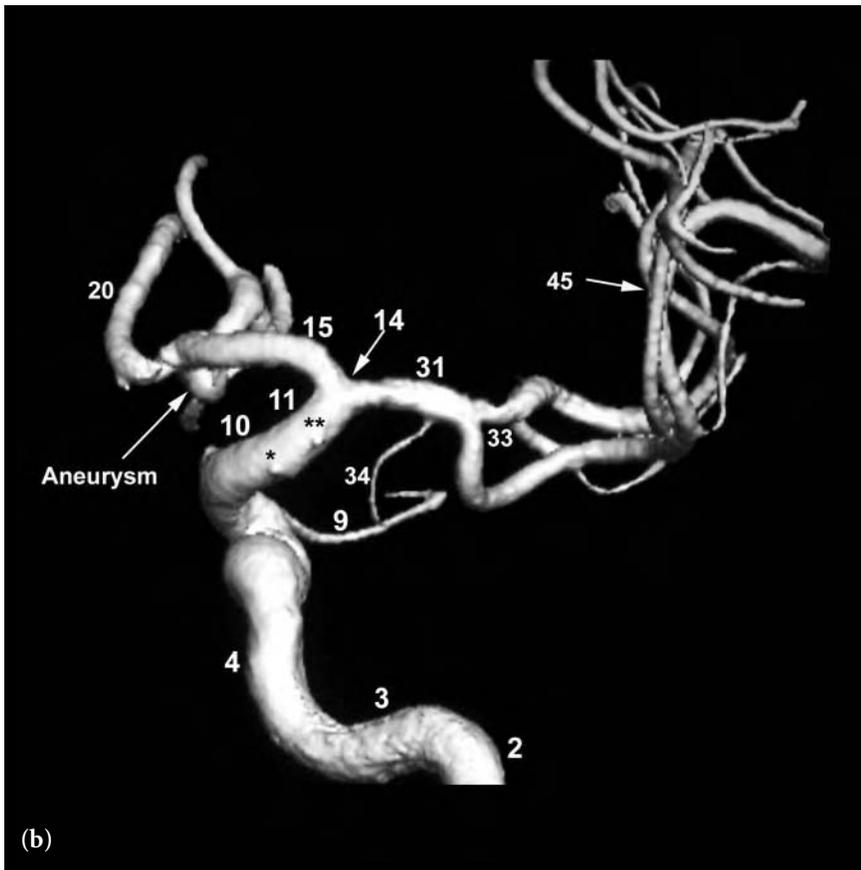

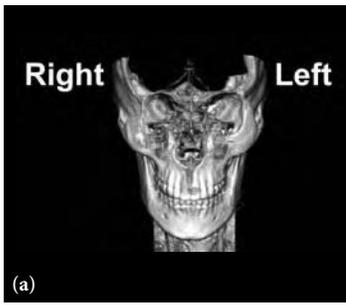

**Fig. 5.20 (a–c)** 3D frontal (a), posterior (b), and medial (c) views following right internal carotid artery injection. These images show an aneurysm arising in the region of the anterior communicating artery. There is a small focal lobulation along the medial surface of the aneurysm that represents an area of weakness of the aneurysm wall and a potential site for rupture. Note the additional tiny aneurysms within the intracavernous segment of the internal carotid artery.

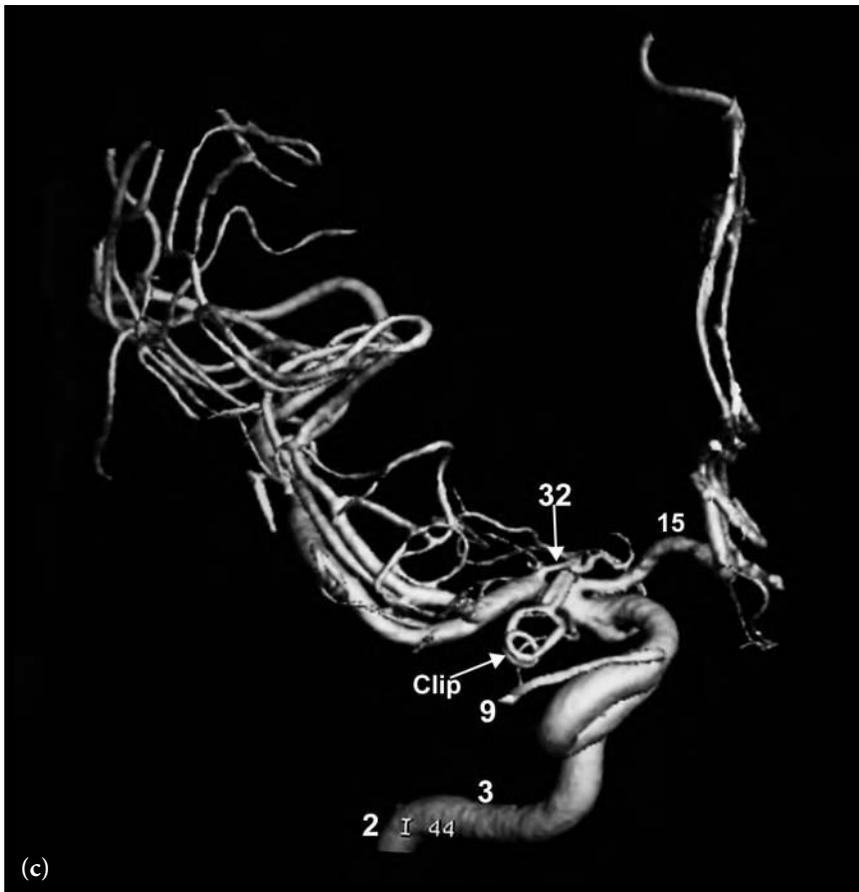

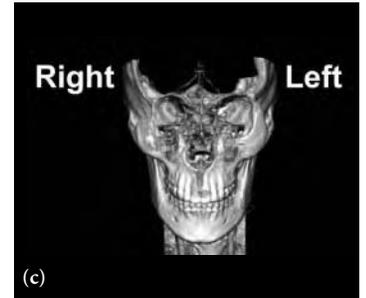

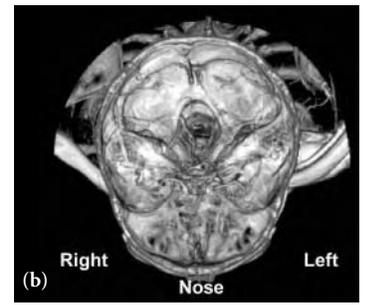

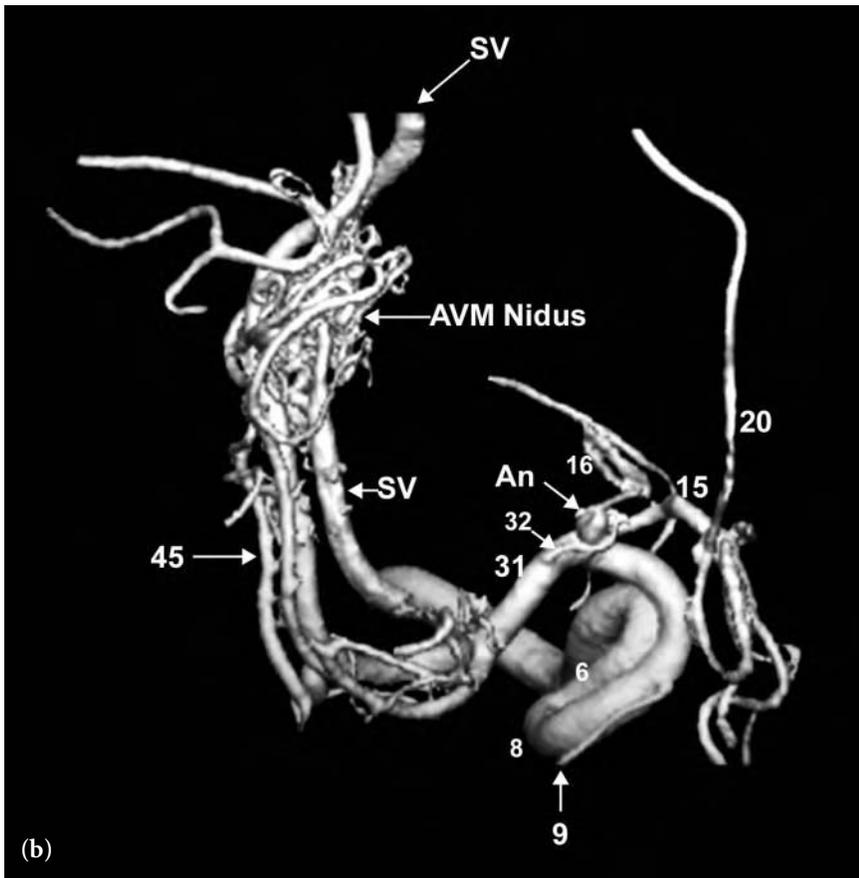

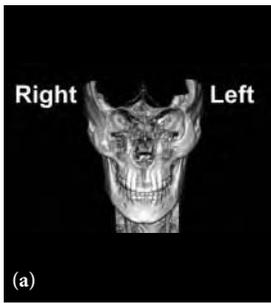

**Fig. 5.28 (a–c)** 3D frontal (a), 3D superior to inferior (b), and frontal post treatment (c) views following right internal carotid artery injection. Images (a) and (b) demonstrate an arterial-venous malformation (avm) in the right sylvian fissure. Partial arterial supply is from the sylvian (insular) branches (45) of the middle cerebral artery. Early venous drainage into a large sylvian vein (SV) can also be seen. Note a small associated aneurysm arising from the proximal A1 segment of the anterior cerebral artery and a lateral lenticulostriate artery draped along the anterior surface of the aneurysm. Following embolization and surgery, image (c) shows the obliteration of the AVM and the successful surgical clipping of the A1 segment aneurysm with the preservation of the adjacent lenticulostriate artery.

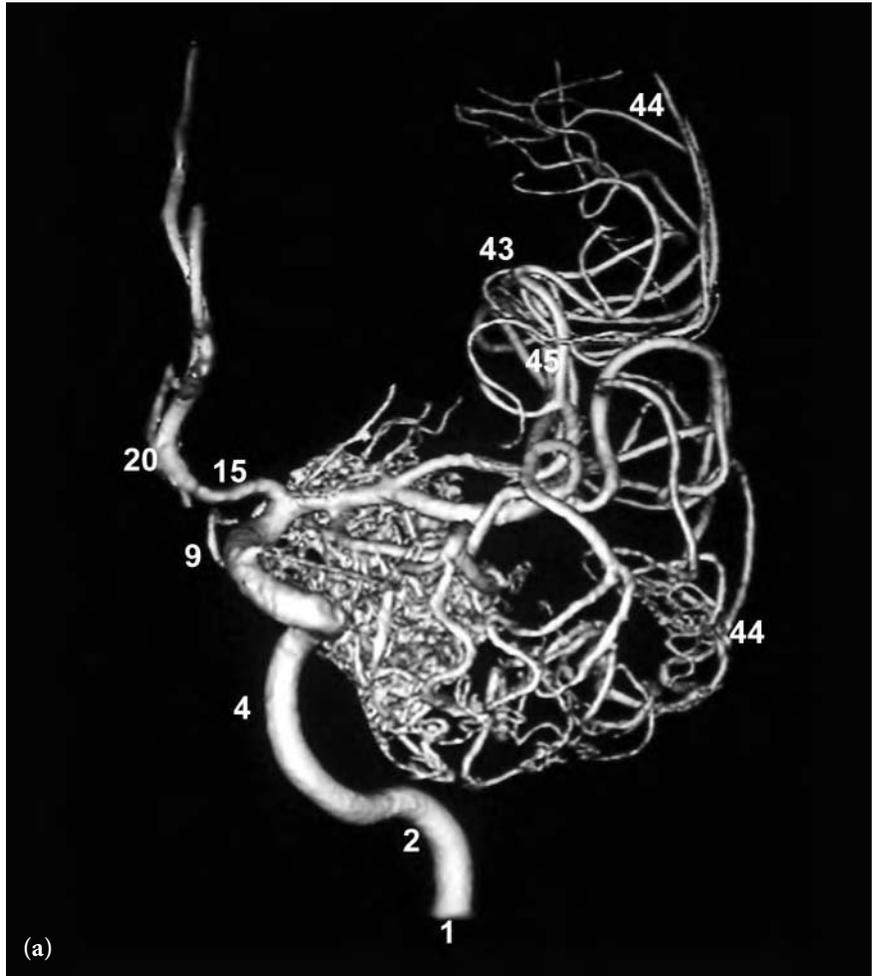

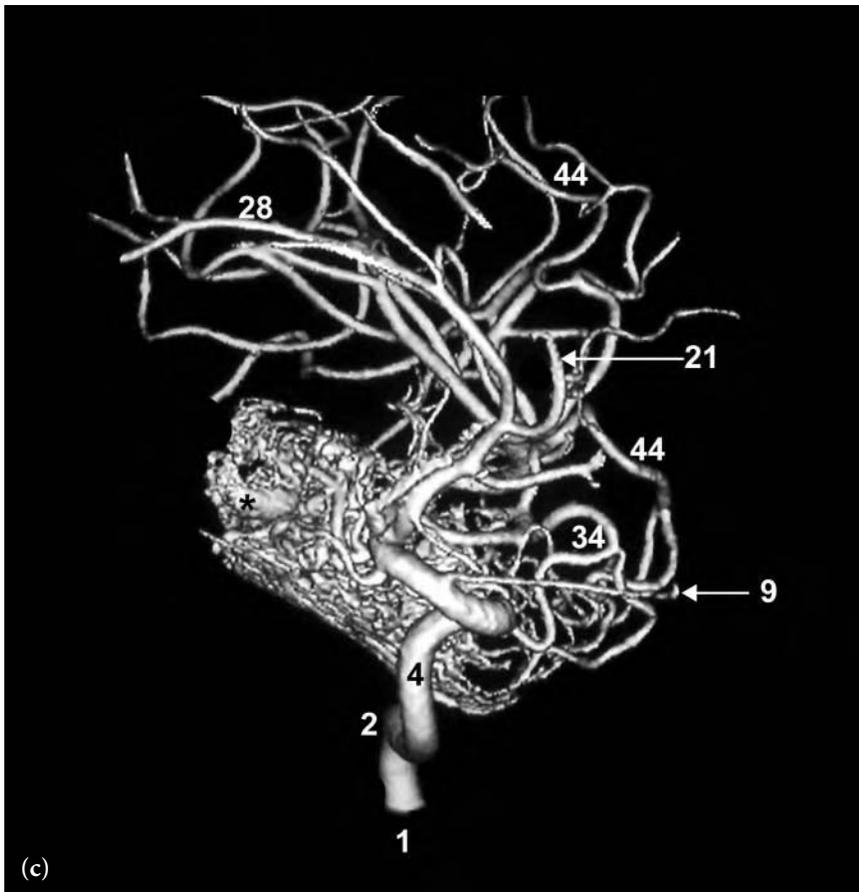

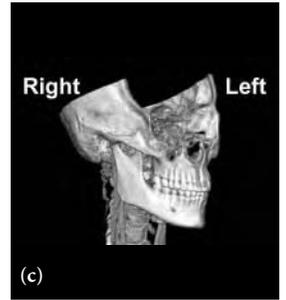

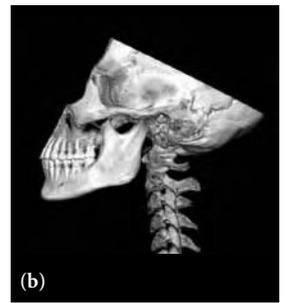

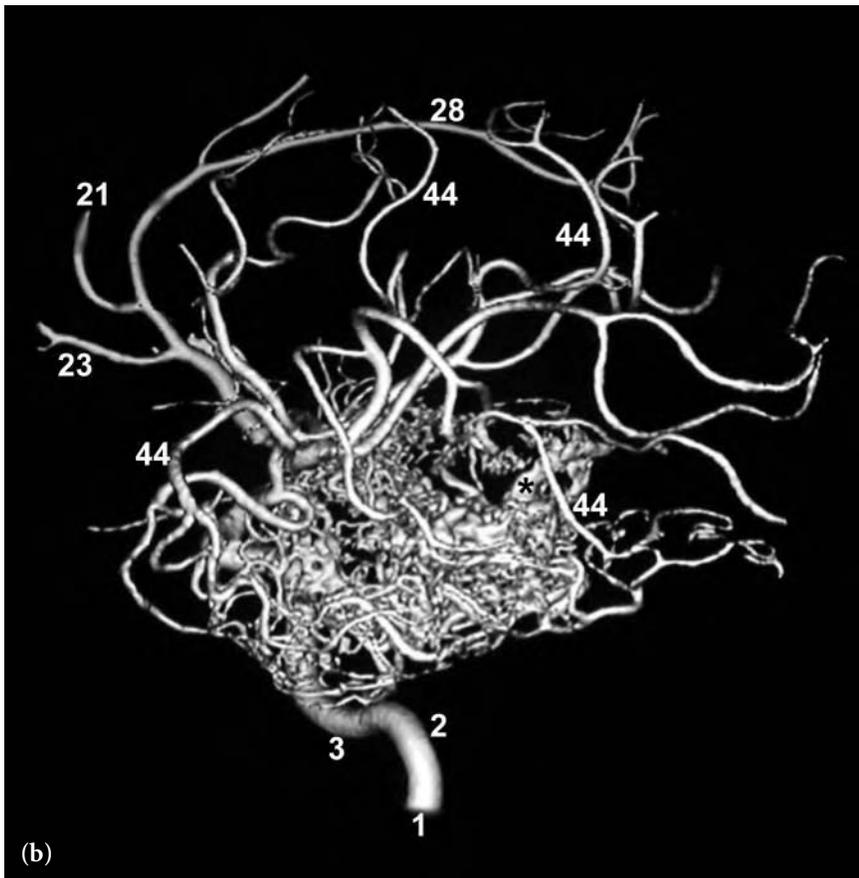

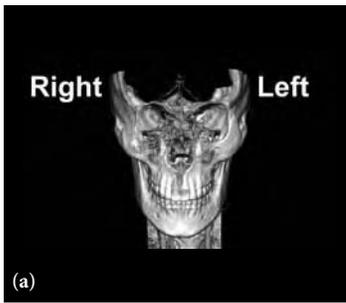

**Fig. 5.29 (a–c)** 3D frontal (*a*), 3D lateral (*b*), and 3D right anterior oblique (RAO) (*c*) views following left internal carotid artery injection. There is a large arterial-venous malformation (avm) in the left temporal lobe. Arterial supply is from multiple anterior and middle temporal lobe branches of the left middle cerebral artery. Note the proximal segment of an early draining vein (\*) along the posterior-superior margin of the AVM nidus. The flat obliquely oriented surface along the inferior surface of the AVM is related to the superior surface of the tentorium cerebelli.

CHAPTER SIX

---

INTRACRANIAL  
VERTEBRAL-BASILAR  
CIRCULATION  
(POSTERIOR  
CIRCULATION)

---

After passing through the foramen magnum the vertebral artery gives rise to numerous branches before uniting with the opposite vertebral artery at the vertebral-basilar junction. Multiple small perforating arteries arise from the distal vertebral artery which supplies the lateral regions of the medulla. The posterior inferior cerebellar artery (PICA) usually arises from the distal vertebral artery 1-2 cm below the vertebral-basilar junction. These arteries are often asymmetric and their size can vary. There is a reciprocal relationship between the size of the PICA and that of the ipsilateral anterior inferior cerebellar artery (AICA) which arises from the basilar artery. When the AICA is large, the ipsilateral PICA is often small or sometimes can be absent. In this situation a large medial branch of the AICA supplies the PICA vascular territory. The PICA divides into branches supplying the ipsilateral cerebellar tonsil, inferior vermis, and the inferior cerebellar hemisphere. Small perforators from the proximal PICA can supply the lateral and posterior medulla. The anterior spinal artery usually arises from the distal 1 cm of the vertebral artery (1). This vessel often unites with the anterior spinal artery branch from the contralateral vertebral artery to form the main anterior spinal artery. The posterior meningeal artery which supplies the falx cerebelli arises from the distal vertebral artery near the foramen magnum. This vessel courses both posteriorly and superiorly.

The vertebral arteries unite to form the basilar artery ventral to the superior medulla/inferior pons. The basilar artery typically runs in the midline but can have a tortuous course. Branches of the basilar artery include paired anterior inferior cerebellar arteries (AICA), small pontine perforator branches, paired superior cerebellar arteries (SCA), and paired posterior cerebral arteries (PCA).

The anterior inferior cerebellar artery (AICA) typically arises from the proximal (inferior) two-thirds of the basilar artery. As discussed above, the AICA has a reciprocal relationship with the ipsilateral posterior inferior cerebellar artery (PICA). The AICA runs laterally, posteriorly, and then

inferiorly around the pons. It continues to traverse the cerebellopontine angle cistern to lie anterior and medial to the facial and acoustic nerves. The AICA often loops into and out of the internal auditory canal (referred to as the “meatal loop”) which is often seen at angiography. The meatal loop gives rise to a small branch supplying the eighth cranial nerve (vestibular cochlear nerve ) called the acoustic branch (internal auditory artery)(2). The AICA then courses laterally to the terminal branches. It then supplies the anterior and inferior cerebellum.

Median and paramedian pontine perforators arise from the basilar artery to supply the medulla and the pons. They can normally be seen only on magnified 2D angiography with selective vertebral injections. Only their most proximal portions are usually seen on three-dimensional rotational angiography (3DRA).

The superior cerebellar artery (SCA) typically arises just proximal (inferior) to the posterior cerebral artery (PCA) from the distal (upper or superior) basilar artery. Both superior cerebellar arteries are almost always present (3). They may appear duplicated (which is seen in some of the atlas images). The SCA runs posterolaterally in the perimesencephalic cistern encircling the brainstem at the junction of the pons and the midbrain encompassing the anterior (or pontine) and ambient (or lateromesencephalic) segments. The SCA then courses into the quadrigeminal cistern for the quadrigeminal segment. The two main terminal branches of the superior cerebellar artery are the vermian and hemispheric branches that supply the superior surface of the cerebellum and cerebellar vermis as well as supply the superolateral aspect of the cerebellar hemispheres, superior cerebellar peduncle, a portion of the middle cerebellar peduncle, and the dentate nucleus (4).

The posterior cerebral artery (PCA) typically originates from the superior basilar artery (basilar tip) at the superior anterior aspect of the pons. The three segments of the PCA are the P1, the P2, and the P3 segments. The P1 segment, also termed the peduncular (or precommunicating) segment, unites the basilar tip to the posterior communicating artery (PCoA) insertion. The P2 segment, also known as the ambient segment, lies in the crural cistern (a portion of the ambient cistern) and runs from the posterior communicating artery insertion around the cerebral peduncle to the posterior aspect of the midbrain. The crural cistern is the portion of the ambient cis-

tern located between the uncus of the temporal lobe and the cerebral peduncle. The P3 segment, also known as the quadrigeminal segment, runs within the lateral aspect of the quadrigeminal cistern curving around the brainstem approaching the opposite P3 segment and then extending posteriorly under the splenium of the corpus callosum. The posterior cerebral artery supplies portions of the temporal, parietal, and occipital lobes as well as the thalamus, midbrain, choroids, and ependyma of the third and lateral ventricles. In 20% of people there is a “fetal” or direct origin of the PCA from the ipsilateral internal carotid artery. In this situation the ipsilateral P1 segment is hypoplastic (small) or absent. Other variations include the duplication of the P1 segment, origin of the superior cerebellar artery from the P1 segment, and common origins of the superior cerebellar artery and P1 segment (5).

Branches of the PCA include perforators to the thalamus and midbrain, ventricular branches to the choroid and ependyma, and cortical branches to the temporal and occipital lobes.

From the P1 segment of the PCA arise the posterior thalamoperforators. The anterior thalamoperforators arise from the posterior communicating artery. The anterior thalamoperforators supply the thalamic nuclei, posterior optic chiasm, proximal optic radiations, posterior hypothalamus, and some of the cerebral peduncle. The posterior thalamoperforators supply the thalamus, subthalamus, as well as nuclei and tracts of the upper midbrain.

From the P2 segment, or less typically the P1 segment of the posterior cerebral artery (PCA), comes the medial posterior choroidal arteries that consists of a single or several small vessels. These vessels run posteriorly and superiorly around the pineal gland and then course anteriorly in the roof of the third ventricle terminating as a sharp curve with terminal vessels ascending into the foramen of Monroe. These vessels take on the appearance of a reverse number “3” on a lateral angiogram. In addition to supplying the choroid and ependyma of the third and lateral ventricles, the medial posterior choroidal arteries supply portions of the thalamus and the pineal gland (6).

The lateral posterior choroidal arteries, a grouping of a single or several small vessels, usually arise from the P2 segment of the posterior cerebral artery (PCA). These vessels course laterally through the choroid fissure and then superiorly in the atrium (trigone) of the lateral ventricle, coursing further posteriorly around the pulvinar of the thalamus. The

lateral posterior choroidal arteries supply the choroid plexus and ependyma of the temporal horn and atrium of the lateral ventricle, portions of the cerebral peduncle, posterior commissure, lateral geniculate body, thalamus, fornix, and caudate (7).

Also arising from the P2 segment of the posterior cerebral artery are a grouping of vessels called the inferior temporal arteries. These arteries provide a cortical supply to the inferior temporal lobe. The posterior temporal branch of the posterior cerebral artery is typically the largest and most commonly seen vessel of the inferior temporal arteries. It courses posteriorly with terminal branches supplying the inferior and medial portions of the posterior temporal lobes. Other less constant temporal lobe branches may arise from the posterior cerebral artery (PCA).

The P3 segment of the posterior cerebral artery runs from the posterior portion of the quadrigeminal plate cistern towards the calcarine fissure giving off the parieto-occipital branch of the posterior cerebral artery, the calcarine branch of the posterior cerebral artery, and the posterior pericallosal (splenial) arteries.

The parieto-occipital branch of the posterior cerebral artery is the largest and most superior of the P3 branches. It arises in the ambient cistern and courses posteriorly into the parietal occipital sulcus to supply the cuneus, precuneus, and superior occipital gyrus. It may also supply the precentral region and superior parietal lobule as well as the visual cortex. (8).

The calcarine branch of the posterior cerebral artery generally arises from the distal posterior cerebral artery and appears just inferior to the parieto-occipital branch. The calcarine branch of the posterior cerebral artery runs into the calcarine sulcus. It supplies portions of the visual cortex, cuneus, and lingual gyrus (9).

With angiography, using a frontal projection, the differentiation of the course of the parieto-occipital branch from the calcarine branch can be made by noting that it is typical that the proximal aspect of the calcarine branch lies laterally to the proximal parieto-occipital artery but courses distally medial to the parieto-occipital artery. The parieto-occipital artery tends to deviate laterally while coursing posteriorly.

The posterior pericallosal arteries, also known as the splenial arteries, are a grouping of small vessels usually originating from the posterior cerebral artery that can arise from the parieto-occipital artery. They initially course

posteriorly and then sweep anteriorly and superiorly about the splenium of the corpus callosum to join with the pericallosal branch of the anterior cerebral artery. These branches can significantly enlarge and provide collateral blood flow to the anterior cerebral artery (pericallosal branch) in cases of severe stenosis or occlusion of the anterior cerebral artery.

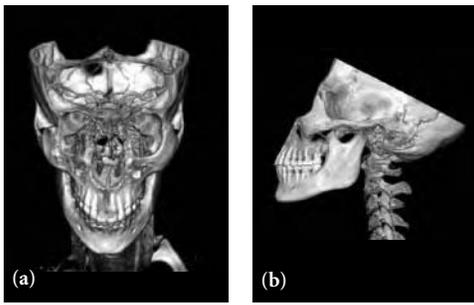

**Fig. 6.6 (a–c)** Frontal 2D (a), frontal 3D (b), and 2D lateral (c) views following left vertebral artery injection. This angiogram was obtained after GDC coiling of an aneurysm arising at the origin of the right AICA. The coil mass (\*\*\*) has been subtracted from the image. No residual filling of the aneurysm is seen. This patient has a fetal/direct origin of the right PCA from the supraclinoid internal carotid artery. This allows for an unobstructed view of the right superior cerebellar artery branches. The different appearance of the branches in (a) versus (b) is related to the angle of the frontal projection which foreshortens the PCA and SCA branches on the frontal 3D image (b). These images show a common variant where a medial branch of the AICA supplies a part or all of the PICA territory. This is called an AICA-PICA.

**Fig. 6.10 (a–e)** 3D frontal (a), posterior (b), and superior (c) pre-stent views and 2D frontal (d) and 3D frontal (e) post-stent views following left vertebral artery injections. The intracranial view of the vertebral basilar circulation is of a patient with severe atherosclerotic vascular disease with severe ulcerated plaque of the mid- to lower-basilar artery with high-grade stenosis. Note the endoluminal impression of the stent on the basilar artery in view (e).

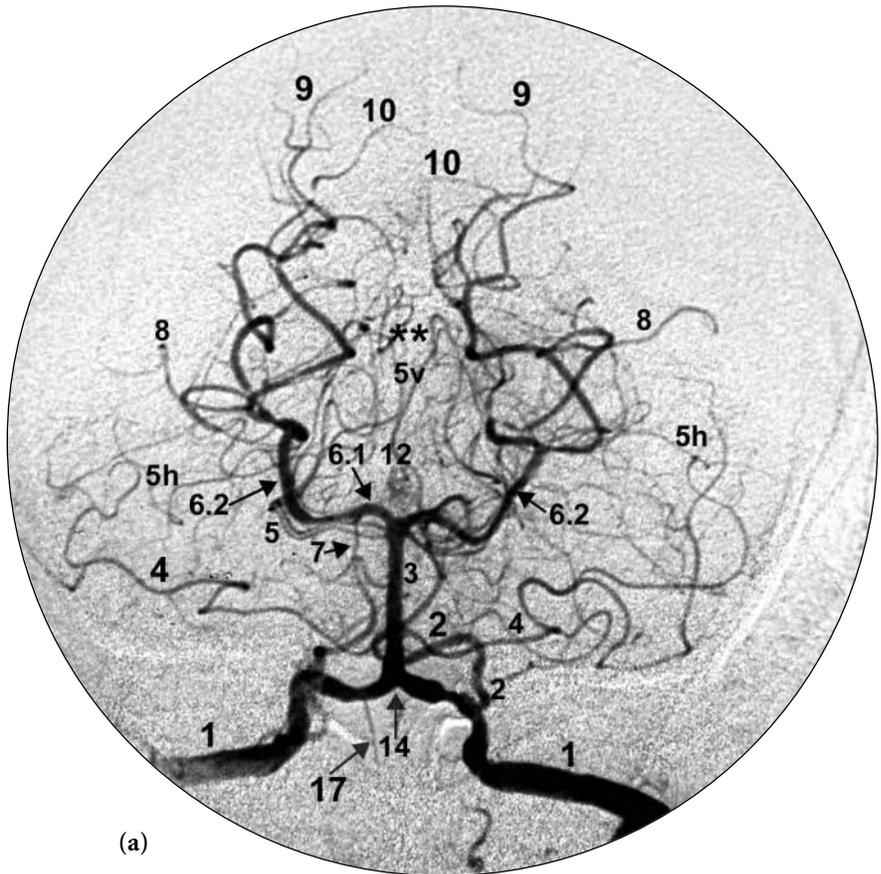

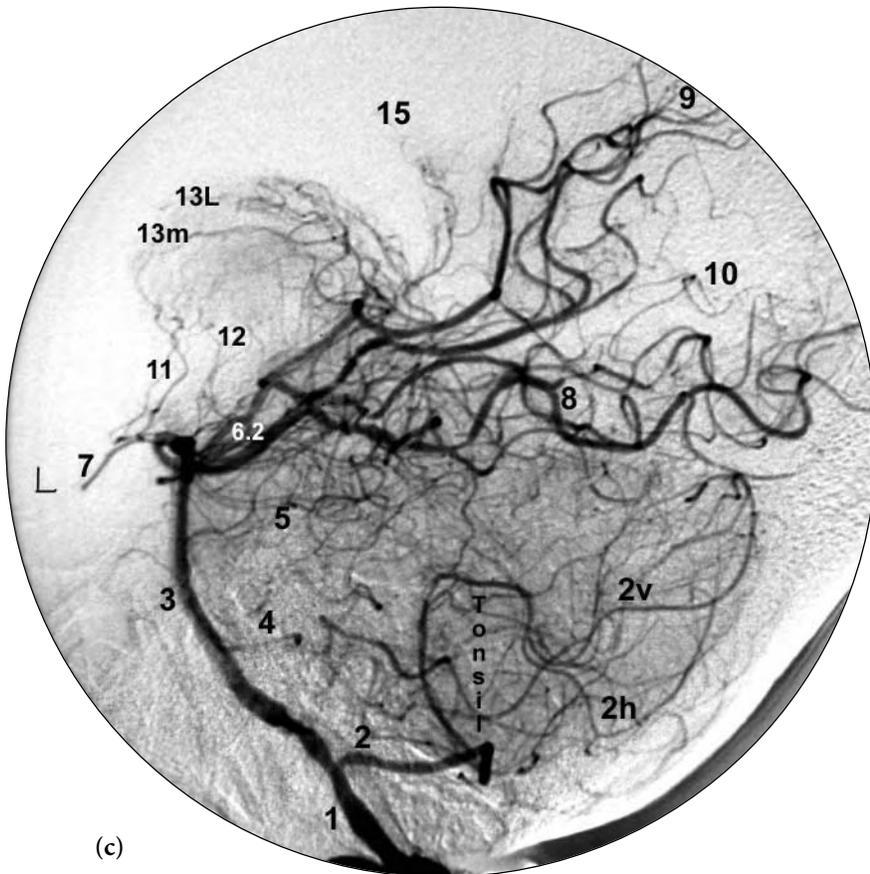

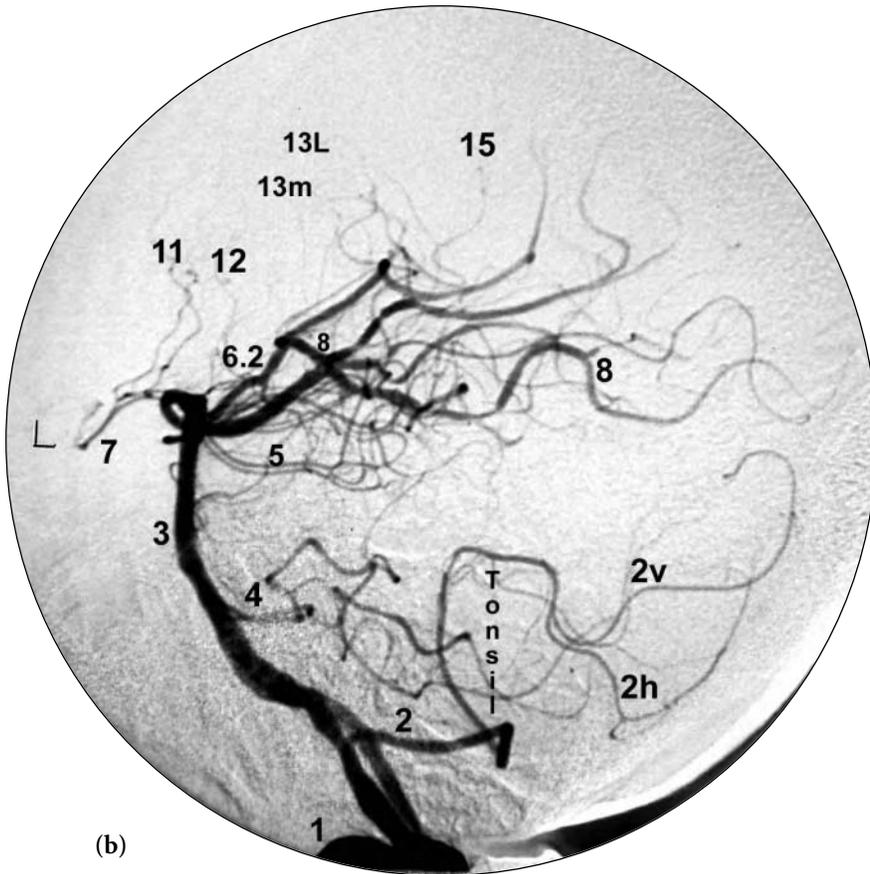

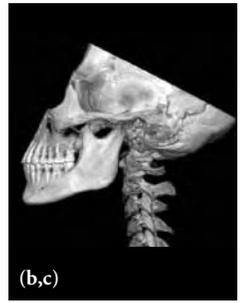

**Fig. 6.11 (a–c)** 2D frontal (a), lateral early arterial (b), and lateral late arterial phase (c) views following left vertebral artery injection. The intracranial view of the vertebral basilar circulation is of a patient with vasculitis. The vasculitis is illustrated by the multifocal areas of stenosis (narrowing). The vascular branching pattern shows a typical appearance of vertebral basilar circulation.

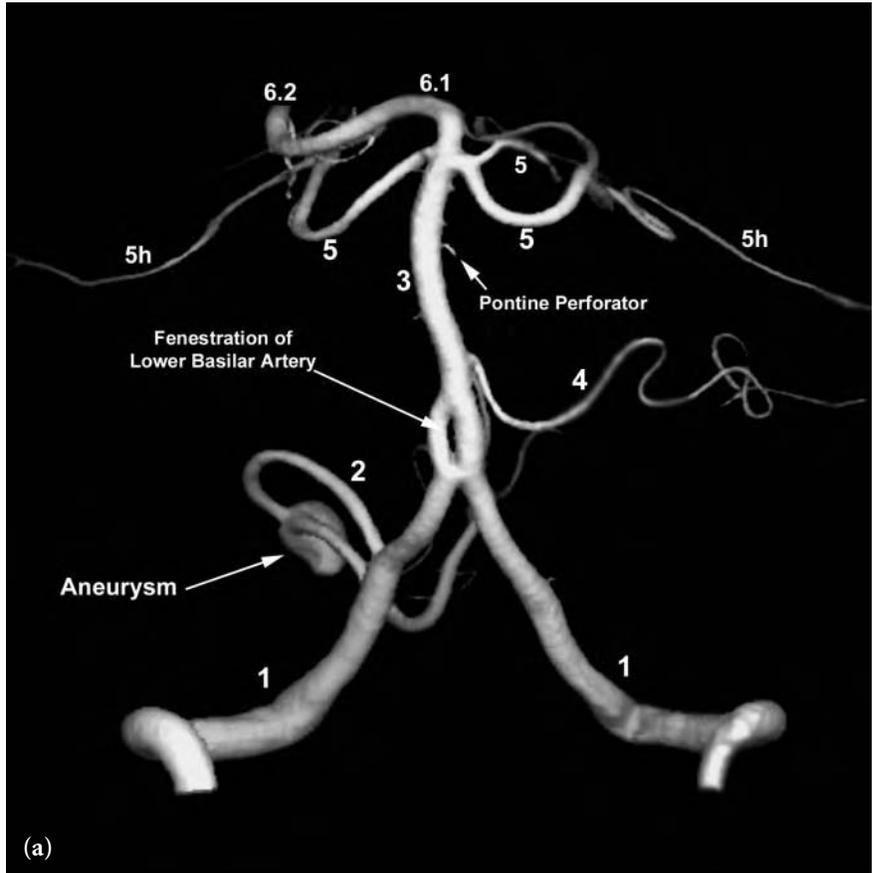

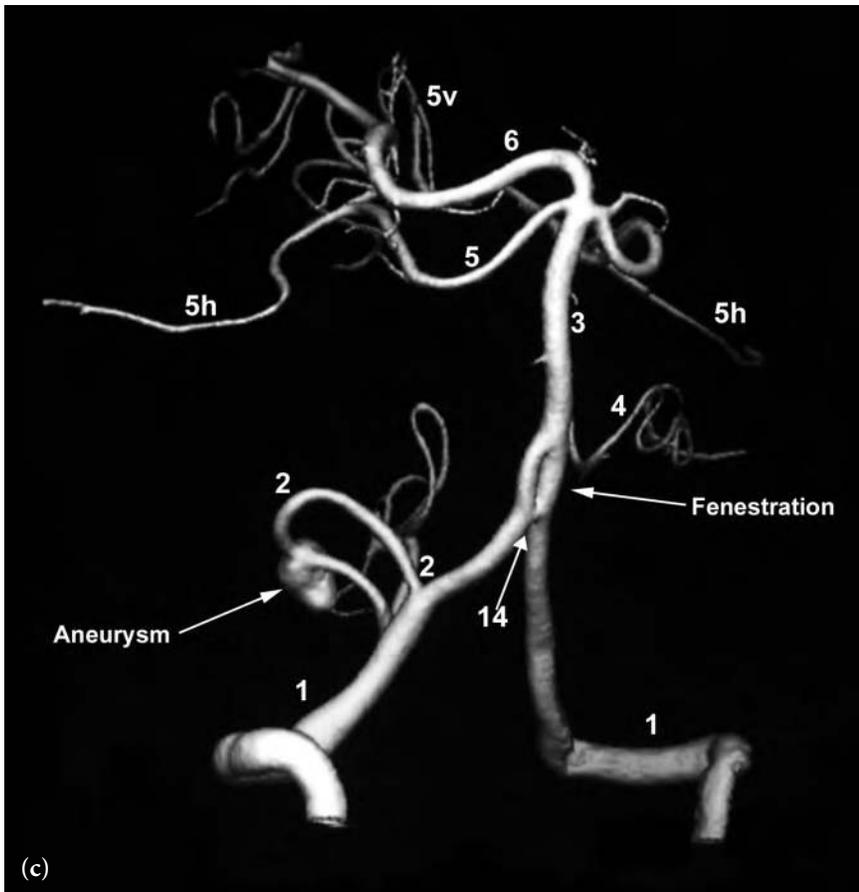

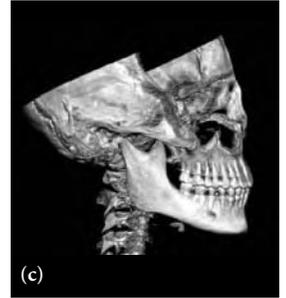

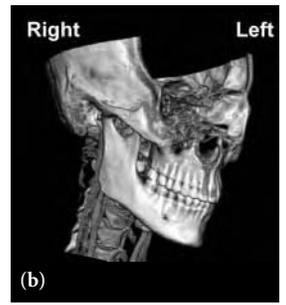

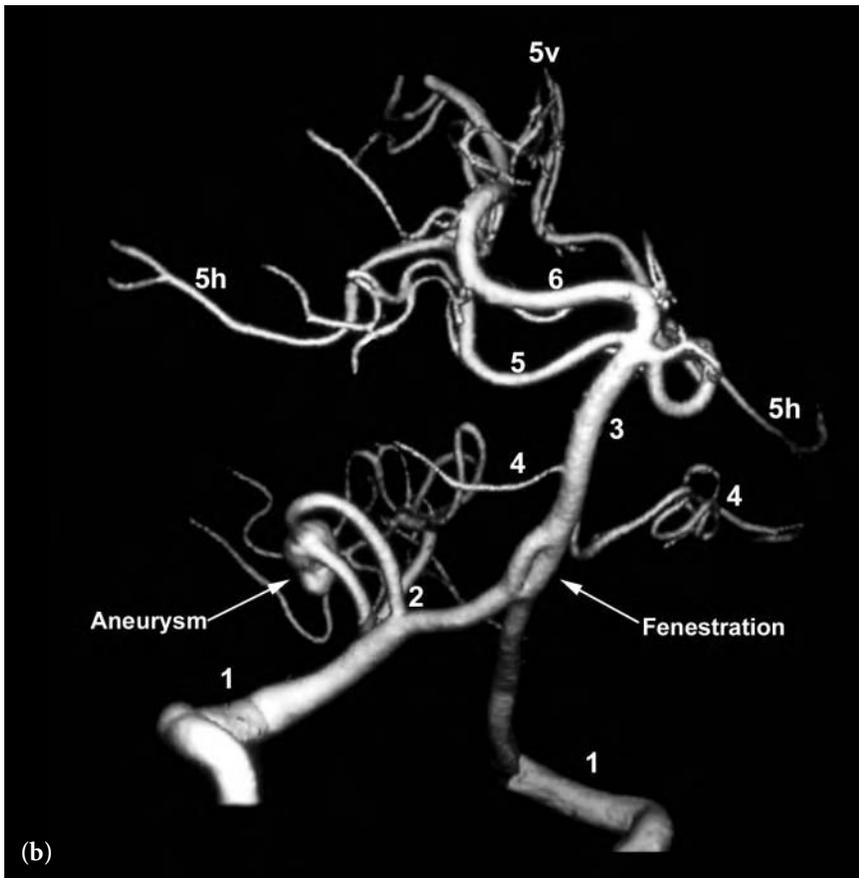

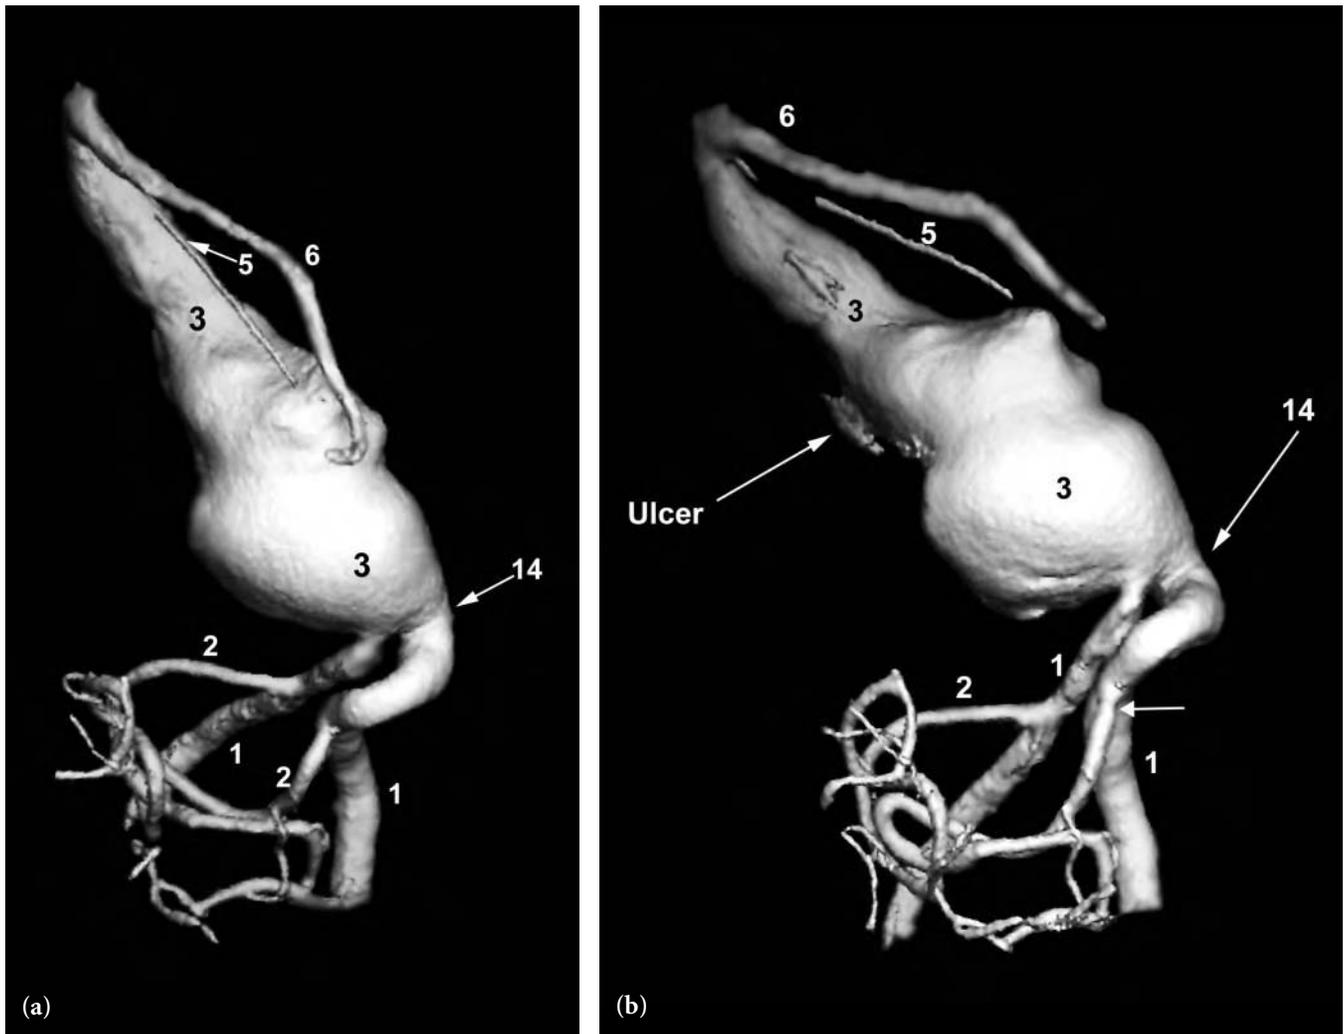

**Fig. 6.14 (a–c)** 3D frontal (a), shallow right anterior oblique (b), and steeper right anterior oblique (c) views following vertebral artery injection. These images show an aneurysm arising from the distal right PICA. Aneurysms more typically arise near the vertebral artery. These images also show normal vascular anatomy with the absence of visualization of the left posterior cerebral artery. This is secondary to a direct/fetal origin from the supraclinoid segment of the ipsilateral internal carotid artery.

**Fig. 6.16 (a–n)** This series of both 2D and 3D images of the vertebral basilar circulation following vertebral artery injections clearly illustrates the morphologic makeup of a typical high-flow arterial-venous malformation (AVM) of the brain. These lesions generally consist of three main elements. The first element is the arterial feeder(s) to the malformation which in this case are posterior temporal artery branches of the posterior cerebral artery. The second element of an AVM is the nidus. The third element consists of draining vein(s). Some of the 2D images have been chosen to match some of the 3D views for a side by side comparison. These comparisons are *d* and *e*, *f* and *g*, and *k* and *l*. Images *m* and *n* were obtained after embolization with glue, particles, and coils and show no evidence of residual arterial venous shunting.

**Fig. 6.18 (a–e)** 3D right anterior oblique (a), steep right anterior oblique (b), frontal (c), right posterior oblique (d), and superior to inferior (e) views of intracranial vertebral basilar circulation following vertebral artery injection. These images demonstrate a high-flow arterial-venous malformation supplied by posterior thalamoperforators and from other branches of the posterior cerebral artery. The nidus is in the region of the expected vein of Galen. The main venous drainage is through the falcine sinus which is an embryologic sinus that normally regresses. This unusual AVM has features of both a vein of Galen malformation and a true parenchymal AVM. Note the two perinidal aneurysms (\*) on the venous side of the AVM nidus, at the nidus-falcine sinus junction.

CHAPTER SEVEN

---

INTRACRANIAL  
VENOUS SYSTEM

---

The venous drainage of the brain and meninges can be divided into the diploic veins, meningeal veins, dural sinuses, as well as the superficial and deep cerebral veins.

The diploic veins are small irregular endothelial-lined channels coursing between the inner and outer tables of the skull. These communicate with the extracranial venous system, the meningeal veins, and the dural sinuses. They are rarely seen using angiography unless enlarged, as in the case of an arterial-venous malformation (AVM).

Emissary veins are conduits between the extracranial scalp veins and the diploic and intracranial venous systems. These veins are valveless and therefore can transmit infection from the extracranial to the intracranial compartment.

The meningeal veins are epidural veins that lie within the dura draining the falx cerebri, the tentorium, and the cranial dura. They run in shallow grooves on the inner table of the skull to communicate with the dural sinuses or traverse extracranially to the pterygoid plexus in the deep face or vertebral plexus around the cervical spine.

The dural sinuses are venous channels lined by endothelium that are formed by opposing layers of dura. They are valveless, trabeculated, and provide the major drainage pathway for the cranial cavity. The major dural sinuses include the superior sagittal sinus, inferior sagittal sinus, straight sinus, occipital sinus, transverse sinuses, petrosal sinuses, sigmoid sinuses, sphenoparietal sinuses, and cavernous sinuses.

The superior sagittal sinus drains the superficial cerebral veins from the medial and lateral surfaces of the cerebral hemispheres and run anteriorly to posteriorly in the midline in a shallow groove along the inner table from the foramen cecum of the crista galli to the torcular Herophili. The torcular Herophili is the confluence of the superior sagittal sinus, the straight sinus, the occipital sinus, and the transverse sinuses. There are many configurations in the appearance of the torcular Herophili which at times may be

duplicated or fenestrated. The anterior portion of the superior sagittal sinus may be congenitally absent. In this case, the superior sagittal sinus is formed by several large cerebral veins overlying the frontal convexity.

The inferior sagittal sinus travels along the inferior free edge of the falx cerebri in an anterior to posterior direction draining into the straight sinus along with the great cerebral vein of Galen. The inferior sagittal sinus drains the anterior portion of the corpus callosum, the medial aspect of the cerebral hemispheres, and the falx cerebri.

The straight sinus runs from the junction of the falx cerebri and the tentorium to the torcular Herophili in a midline superior-anterior to inferior-posterior course. The straight sinus may be duplicated in 7%–15% of the cases (1). The straight sinus is the main conduit transmitting venous blood from the deep venous system towards the more superficial dural sinuses.

The occipital sinus is typically the smallest of the dural sinuses, originating at the posterior margin of the foramen magnum and draining superiorly to the torcular Herophili. It can communicate with the internal jugular vein or with the vertebral venous plexus. The marginal sinus runs along the lateral margins of the foramen magnum and communicates with the occipital sinus along the posterior margin of the foramen magnum. The marginal sinus communicates anteriorly with the basilar venous plexus on the superior surface of the clivus. The marginal sinus also communicates with the internal jugular veins and the jugular bulbs laterally via small venous connections (2).

The paired transverse sinuses begin at the torcular Herophili and run anterolaterally to become the sigmoid sinuses when turning inferiorly and medially at the posterior aspect of the petrous temporal bones. The transverse sinuses run in a groove along the inner table of the calvarium and are enveloped within the peripheral edge of the tentorium. In addition to draining the superior sagittal sinus and the straight sinus from the torcula, the transverse sinuses also drain the supratentorial veins from the temporal and occipital lobes as well as the cerebellar veins and the superior petrosal sinuses. In 25% of the cases, the transverse sinuses are unequal in size (3). An atretic segment may be seen in 5% of the cases (4). In most people the superior sagittal sinus drains preferentially into the right transverse sinus, while the deep venous system through the straight sinus drains preferentially into the left transverse sinus.

The superior petrosal sinus extends from the posterior aspect of the cavernous sinus at the petrous apex to the sigmoid sinus along a dural attachment of the tentorium to the petrous temporal bone. It provides venous drainage from the pons, upper medulla, cerebellum, and middle ear (5).

The inferior petrosal sinus runs inferiorly along the petro-occipital fissure from the posterior aspect of the cavernous sinus (near the petrous apex). It traverses the pars nervosa compartment of the jugular foramen before emptying into the jugular bulb in the pars vascularis compartment. The paired inferior petrosal sinuses are interconnected with the basilar venous plexus of the clivus and the intercavernous sinus (or circular sinus) to communicate with the cavernous, superior petrosal, marginal, and occipital sinuses.

The sphenoparietal sinus drains the superficial middle cerebral vein running along the greater sphenoid wing to the cavernous sinus. The sphenoparietal sinus often anastomoses with the basal vein of Rosenthal.

The paired cavernous sinuses are irregularly paired venous spaces that lie on either side of the sphenoid bone in the central skull base region. They lie on either side of the sella turcica, which houses the pituitary gland. The cavernous sinuses represent a complex interconnection of the intracranial and extracranial venous structures. Anteriorly the cavernous sinuses communicate with the superior and inferior ophthalmic veins as well as the sphenoparietal sinus. Laterally and inferiorly the cavernous sinuses communicate with the pterygoid plexus of the deep face through the foramen ovale. The cavernous sinuses are interconnected medially by the intercavernous sinuses (or circular sinuses) which run in the diaphragma sellae along the roof of the sella turcica. The cavernous sinus communicates posteriorly with the transverse sinus via the superior petrosal sinus and the internal jugular veins via the inferior petrosal sinuses. Contained within the cavernous sinus are the cavernous portions of the internal carotid arteries and the abducens nerve (CN VI). Portions of the oculomotor nerve (CN III), the trochlear nerve (CN IV), and the first and second divisions of the trigeminal nerve (V1 and V2) lie between dural leaves of the lateral cavernous sinus wall. The abducens nerve lies in close proximity to the lateral aspect of the horizontal intracavernous segment of the internal carotid artery. Patients may present with isolated sixth nerve palsy (inability to abduct the eye) in cases of aneurysms of the horizontal intracavernous internal carotid artery.

The superficial cerebral veins run along the surface of the brain draining cortical gray matter and portions of white matter. There is a good deal of variability in the course, size, and number of these veins. In general, the superficial cerebral veins have a spoke-like pattern converging inferiorly towards the sylvian fissure and superiorly towards the superior sagittal sinus. Typically, the superficial cerebral veins drain inferiorly through the “sylvian” or superficial middle cerebral vein, posteriorly and laterally through the anastomotic vein of Labbé, or superiorly through the anastomotic vein of Trolard or other unnamed superiorly directed superficial veins.

The superficial middle cerebral vein drains the opercular areas adjacent to the sylvian fissure coursing anteriorly and inferiorly around the temporal lobe tip to drain into the cavernous or sphenoparietal sinus. The superficial middle cerebral vein communicates with the deep cerebral system through the uncal, insular, and basal veins as well as communicating with other superficial veins and dural sinuses.

Dominant superiorly and inferiorly directed superficial veins drain into the superior sagittal sinus and the distal transverse sinus, respectively. The largest superiorly directed vein is called the anastomotic vein of Trolard. The anastomotic vein of Labbé represents the largest inferiorly and posteriorly directed superficial anastomotic vein coursing laterally over the surface of the temporal lobe and draining the temporal lobe which typically drains posteriorly into the distal transverse sinus. This is an important source of venous outlet for the temporal lobe. Care is taken during endovascular or operative procedures to ensure its integrity unless there are mitigating circumstances necessitating its sacrifice. If a normal vein of Labbé is disconnected, it can result in venous infarction of the temporal lobe. However, if the vein of Labbé is arterialized from a dural fistula or other etiology it can generally be sacrificed without troublesome consequences.

The deep supratentorial cerebral veins drain the hemispheric white matter, basal ganglia, corpus callosum, pineal area, midbrain, portions of the limbic system, and the thalamus centrally via medullary veins into the subependymal veins coursing along the medial walls of the lateral ventricles. Numerous small deep medullary veins originate 1 to 2 cm below the cortical grey matter (6) and course through deep cerebral white matter in a perpendicular direction to converge into larger tributaries that drain into the internal cerebral vein and the great cerebral vein of Galen. These tributaries are

divided into medial and lateral draining subependymal veins. In general, medullary veins are not visualized on routine 2D or 3D angiography. They may be seen on 2D angiography in situations where they are enlarged or more prominent as a result of increased blood flow.

The medial subependymal veins consist of the anterior septal veins, the posterior septal veins, and the common atrial veins. The anterior septal vein drains the convergence of medullary veins of the anterior frontal lobe and then travels posteriorly along the septum pellucidum and under the fornix to join the thalamostriate vein and the choroidal vein.

The lateral subependymal veins consist of the thalamostriate, anterior caudate, and direct lateral veins. Formed from the union of the anterior caudate vein and the terminal vein, the thalamostriate vein is the largest of the lateral subependymal veins. The thalamostriate vein drains the posterior frontal and anterior parietal lobes, caudate nucleus, and the internal capsule. The thalamostriate vein is usually a major supplier of venous blood to the internal cerebral veins. The direct lateral vein runs along the lateral wall of the atrium to receive drainage from the posterior temporal and parietal lobes typically course medially over the thalamus to join the internal cerebral vein. The inferior ventricular vein generally begins in the posterior aspect of the body of the lateral ventricle. It runs inferiorly along the anterior wall of the atrium of the lateral ventricle and then anteriorly along the roof of the temporal horn before turning medially. The inferior ventricular vein drains into the basal vein of Rosenthal after penetrating the choroidal fissure.

The internal cerebral veins are paired, originating at the junction of the anterior septal vein and the thalamostriate vein. The internal cerebral veins then course posteriorly in the roof of the third ventricle between the leaves of the velum interpositum. Receiving numerous small tributaries along their course and initially running side by side, the internal cerebral veins deviate from the midline at the pineal recess and proceed along the superolateral surface of the pineal body to converge at the level of the inferior splenium of the corpus callosum to form the great cerebral vein of Galen. Just before the convergence of the internal cerebral veins, the basal veins of Rosenthal join their ipsilateral internal cerebral veins.

The venous angle is defined as the junction of the thalamostriate vein with the internal cerebral vein and is typically located at the foramen of

Monro. A false venous angle is determined by the absence of the anteriorly, slightly ascending segment of the internal cerebral vein, the absence of the frontally convex curve seen in the thalamostriate vein where it joins the internal cerebral vein, and the increased length of the anterior and longitudinal caudate veins (7).

The basal vein of Rosenthal begins in the supra-sellar cistern, medial to the uncus. It receives venous flow from the olfactory veins, insular veins, the deep middle cerebral vein, and the inferior striate veins. As it runs posteriorly, the basal vein of Rosenthal extends from the supra-sellar cistern (medial to the uncus) into the crural cistern, lateral to the cerebral peduncle. The crural cistern lies between the uncus and the cerebral peduncle. It subsequently drains into the ipsilateral internal cerebral vein or great cerebral vein of Galen. It rarely directly enters the straight sinus (8). The basal vein of Rosenthal provides venous drainage to the orbital surface of the frontal lobe, insula, medial temporal lobe, hypothalamus, striatum, thalamus, and midbrain. On frontal projection, the basal vein of Rosenthal has the appearance of a “leg of a frog lying on its back with its toes pointing anterolaterally”. The “knee of the frog’s leg” represents its lateral aspect as it courses around the cerebral peduncles. The “ankle” represents the more anterior aspect of the basal vein where it lies medial to the uncus of the temporal lobe (9).

The great cerebral vein of Galen is a single “U” shaped vessel that runs under and then posterior to the splenium of the corpus callosum. It joins with the inferior sagittal sinus to form the straight sinus at the apex of the tentorial incisura. The vein of Galen receives tributaries from the inferior sagittal sinus, pericallosal veins, internal occipital veins, the posterior fossa veins, and occasionally the basal vein of Rosenthal.

The infratentorial venous system is discussed in three groups: the superior or Galenic draining group, the anterior or petrosal draining group, and the posterior or tentorial draining group.

The superior group of posterior fossa veins includes the precentral cerebellar vein, the superior vermian vein, the posterior and lateral mesencephalic veins, and the anterior pontomesencephalic veins. The precentral cerebellar vein is formed by brachial veins medially coursing over the brachium pontis. The precentral vein then runs in the fissure between the lingual and the central lobule of the vermis to terminate in the vein of Galen.

The superior vermian vein typically originates near the declivity of the vermis coursing anteriorly and superiorly over the superior culmen. It then arcs slightly inferiorly just anterior to the vermis and finally runs superiorly to terminate in the vein of Galen. The posterior mesencephalic veins are paired veins arising from the lateral aspects of the respective cerebral peduncles from peduncular veins to then traverse around the brainstem within the ambient cistern, to then empty into the vein of Galen. The lateral mesencephalic vein runs superiorly and longitudinally along the mesencephalon to join the brachial vein and the posterior mesencephalic vein. The position of the lateral mesencephalic vein marks the junction of the tegmentum and the cerebral peduncle (10). The anterior pontomesencephalic vein or plexus of veins runs longitudinally and superiorly along the surface of the pons and mesencephalon. This vein outlines the ventral surface of the brainstem. It is a more accurate indicator of the position of the ventral brainstem than the position of the basilar artery, which can be tortuous, coursing laterally away from the ventral aspect of the brainstem. The anterior pontomesencephalic vein or plexus of veins typically curve into the interpeduncular fossa, demarcating the cerebral peduncles' undersurface and then drains into the basal vein of Rosenthal or the posterior mesencephalic vein.

The anterior or petrosal group of draining veins includes the petrosal trunk (petrosal vein) and the brachial veins to provide venous drainage for portions of the cerebellum, pons, and medulla. The petrosal trunk (petrosal vein) originates in the cerebellopontine angle cistern. It is a short vessel that receives many small venous tributaries from the pons, cerebellar hemispheres, brain stem, and the fourth ventricle. The petrosal trunk (petrosal vein) runs anteriorly and laterally below the fifth cranial nerve (trigeminal nerve) to drain into the superior petrosal sinus just above the porus acousticus. The brachial veins are paired venous vessels that typically empty into the precentral cerebellar vein or may extend laterally over the brachium pontis to drain into the petrosal vein. The brachial veins are best visualized on the frontal projection as an inverted "V".

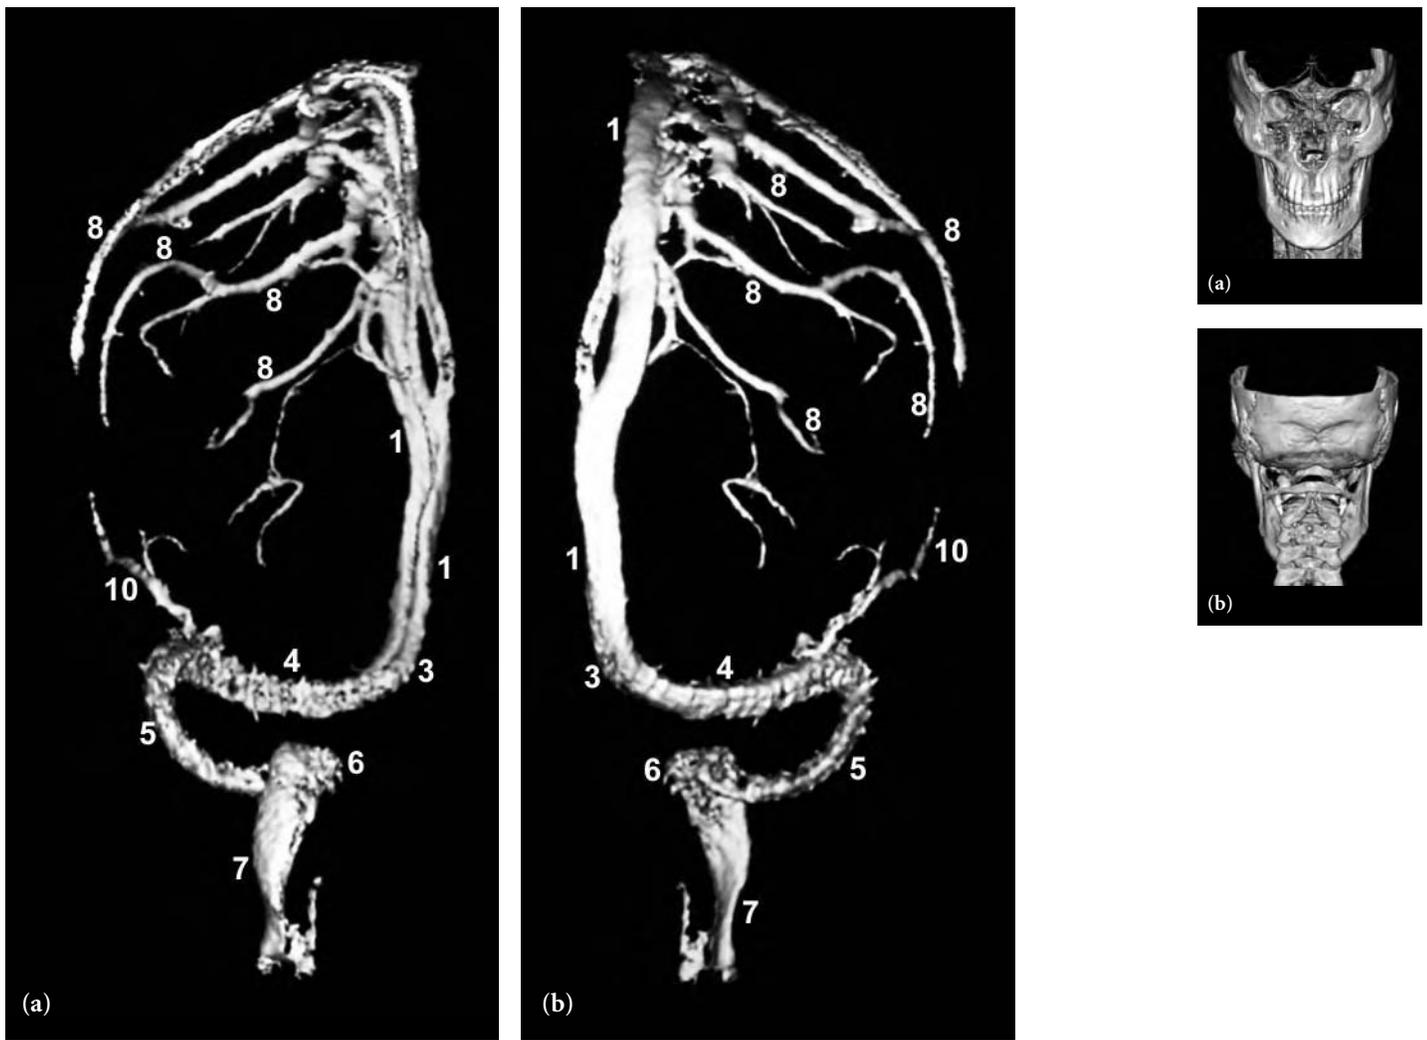

The posterior draining group includes the inferior vermian veins and the inferior hemispheric veins. The inferior vermian veins are paired vessels that are paramedian in location originating at or near the pyramidal lobule by numerous small tributaries from the cerebellar tonsils. The inferior vermian veins run posteriorly and superiorly along the inferior vermian

surface, receiving numerous small tributaries to terminate in venous sinuses within the tentorium, the straight sinus, or the transverse sinus adjacent to the torcular Herophili. The inferior hemispheric veins provide venous drainage for the posterior inferior cerebellar hemispheres and drain into the inferior vermian veins or into a transverse sinus.

Angiographic analysis of the posterior fossa veins is challenging because of the large number of venous structures, the small compartment in which they reside, and the numerous variations of what is considered normal which can exist.

**Fig. 7.5 (a–o)** 2D lateral views of venous phase circulation following carotid artery injections in multiple patients. These images show the marked variability in the intracranial venous anatomy which is normal and to be expected. This series of images shows the normal variability in the size of the veins of Trolard and Labbé as well as showing the wide but normal differences in the appearance of the deep venous system. Note the variation in the appearance of the deep venous system that results in the “true” and “false” venous angles in images *c-f*, *h*, *i*, *k-m*. Note the absence of vascular structures just below the superior sagittal sinus in image *n*. This is secondary to a severe developmental hypoplasia of the A1 segment of the anterior cerebral artery on the injected side. This vascular territory would be visualized when the opposite carotid artery is injected. During the venous circulation phase, with time you normally visualize the deep venous system to a better advantage after the normal washout of the superficial veins. This is demonstrated in the views in figures *b*, *c*, *g*, *h*, *j*, and *k*.

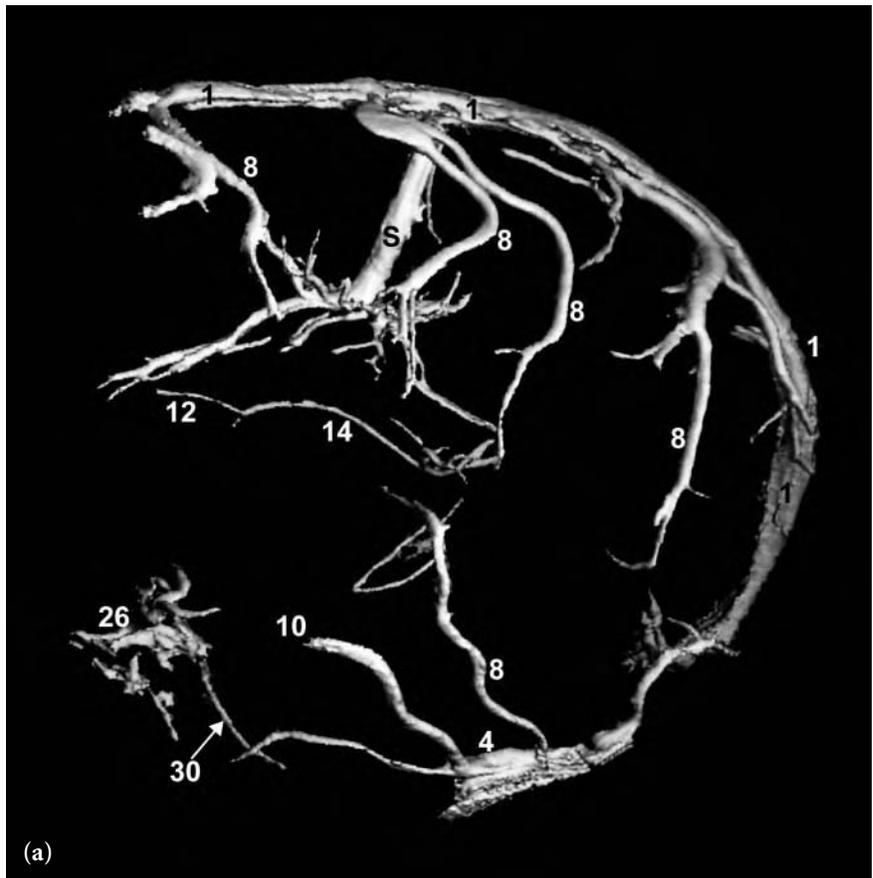

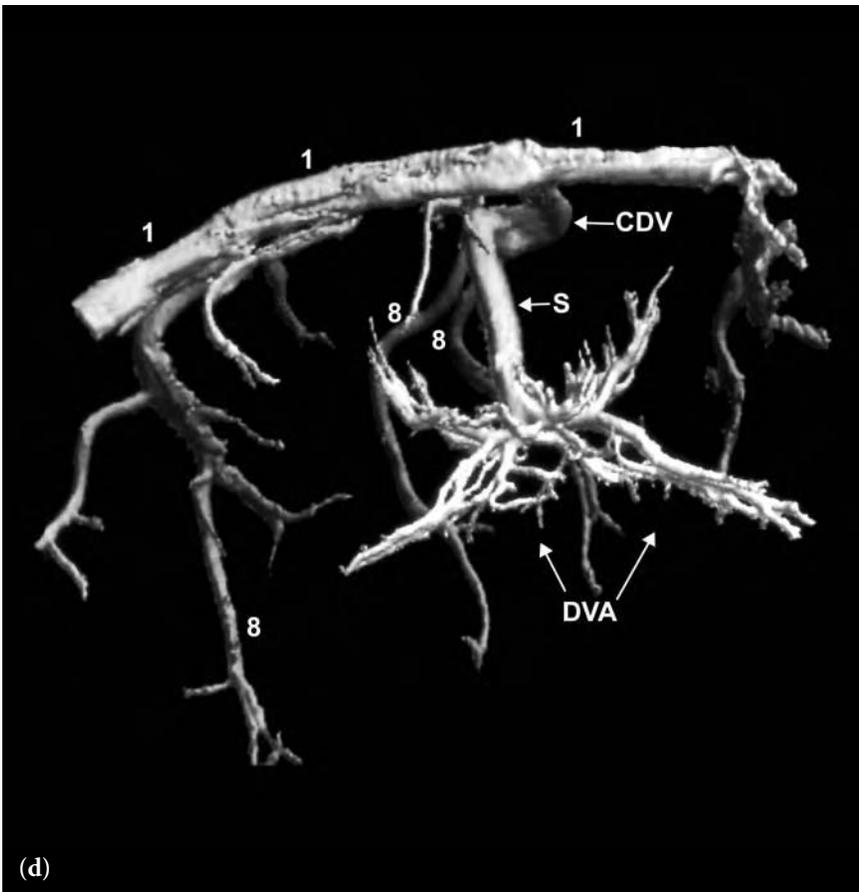

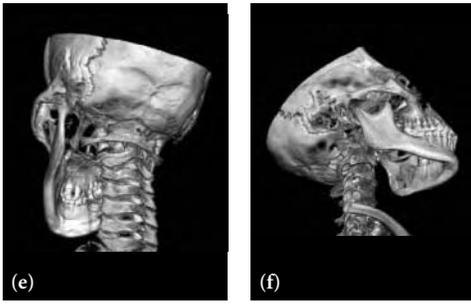

**Fig. 7.10 (a–g)** 3D left lateral (a), left posterior oblique with angulation (b), segmented left lateral (c), segmented right lateral view with angulation (d), and complex angle views (e–g) of venous phase circulation following left carotid artery injection. This is the same patient that appears in Figures 7.8 and 7.9. These images confirm the appearance of a large developmental venous anomaly (DVA). The ability to visualize the path of drainage into the superior sagittal sinus with multiple complex angles utilizing the 3D technique helps show the large DVA draining through a vein (CDV). This is also the pathway of venous drainage for two prominent superficial cortical veins. The cavernous malformation adjacent to the DVA may have resulted from venous congestion of the DVA.

CHAPTER EIGHT

---

CIRCLE OF WILLIS

---

No atlas of neurovascular anatomy would be complete without a description of the circle of Willis. The circle of Willis is known to almost everyone who has an interest in or who has studied the intracranial vascular system. The circle of Willis is a polygonal-shaped collection of arteries at the base of the brain that provides a pathway of communication between the anterior (carotid) and the posterior (vertebral-basilar) circulations. Images demonstrating the components of the circle of Willis are seen throughout this text. This collection of arteries is especially important in providing a pathway for collateral circulation in cases of intracranial vascular occlusions. Unfortunately a complete circle of Willis is present in only approximately 18% of the population (1). The “classical” circle of Willis includes both internal carotid arteries, both A1 anterior cerebral artery segments, both posterior communicating arteries, both P1 posterior cerebral artery segments, and the anterior communicating artery. In most cases one or multiple portions of the circle of Willis are developmentally/congenitally hypoplastic or absent. Common congenital variations include hypoplasia or absence of the A1 anterior cerebral artery segment (25%), hypoplasia or absence of a posterior communicating artery (32%), or hypoplasia or absence of the P1 posterior cerebral artery segment with fetal/direct origin from the ipsilateral supraclinoid segment of the internal carotid artery (15–22%). Additionally, the anterior communicating artery may be fenestrated or absent (9%). An incomplete circle of Willis is the norm rather than the exception and often results in the isolation of a vascular territory. This can have serious implications due to the limiting of collateral flow in cases of vascular occlusive disease (2).

The circle of Willis gives rise to many small branch vessels including the lenticulostriate arteries from the A1 anterior cerebral artery and the anterior thalamoperforating branches that arise from the posterior communicating arteries. The lenticulostriate arteries supply the superior sur-

faces of the optic nerves and chiasm, anterior hypothalamus, septum pellucidum and medial anterior commissure, pillars of the fornix, and the anterior inferior striatum. The anterior thalamoperforating branches supply the posterior portion of the optic chiasm, optic tract, posterior hypothalamus, a portion of the cerebral peduncles, the mammillary bodies, and the thalamic nuclei (3). Some of these small basal perforating vessels can be seen on high-resolution (1024 x 1024 matrix) two-dimensional digital subtraction angiography (2D DSA), especially if a magnification technique is used. They are not typically visualized on three-dimensional rotational angiography (3DRA) unless they are pathologically enlarged.

Aneurysms are a frequent pathology of the circle of Willis with 90% of all intracranial aneurysms arising near the origin of the vessels forming the circle of Willis. Thirty to thirty-five percent of the aneurysms arise near the anterior communicating artery and 30–35% arise in close proximity to the origin of the posterior communicating artery (4).

It is common practice to assess the integrity of the circle of Willis during angiographic procedures for a variety of clinical indications. During the procedure if it is unclear whether the anterior communicating artery provides cross-filling from one side to the other, maneuvers can be utilized to provoke visualization of this important segment of the circle of Willis. During the initial bolus of contrast, external compression of the neck overlying the carotid artery on the side opposite the carotid artery being injected can enhance the ability to see if the anterior communicating artery is functionally present. Compression of the neck results in a transient decrease in arterial blood pressure on the side being compressed. If the anterior communicating artery is functionally present then contrast injected on the opposite side would opacify the anterior communicating artery and variable degrees of the intracranial carotid (anterior) circulation. In a similar fashion, during angiography it is possible to assess the integrity of the posterior communicating artery by compressing one side of the neck overlying the carotid artery during the initial few seconds of selective vertebral artery injection. If the posterior communicating artery is functionally present on the side being compressed you will opacify this vessel via contrast traveling through the basilar artery into the P1 segment of the posterior cerebral artery and

then through the posterior communicating artery. This maneuver can also be of value in the assessment of carotid cavernous sinus fistulas. The morphologic detail of the fistulous connection can often be better evaluated by this technique as opposed to the injection of contrast into the carotid artery on the side of the arterial-venous fistula from below. The latter often results in the flooding of contrast through the high-flow arterial-venous communication which often obscures adequate assessment of the fistulous site.

anterior temporal lobe branches  
of, 20–22, 102, 106–109,  
122–133, 140–142,  
145–149, 152–156  
bifurcation/trifurcation of,  
20–22, 99–100, 102,  
104–107, 110–119,  
121–156, 158–159  
central rolandic branches of,  
97
- M1 segment of, 20–22, 99–100,  
103–112, 114–131,  
134–151, 154–159  
middle temporal branches of,  
97, 101, 102  
opercular branches of, 20–21,  
97, 99–102, 104–111,  
124–126, 132–133,  
143–149, 152–153, 157  
operculofrontal branches of, 97,  
103  
orbitofrontal branch of, 20, 22,  
97, 99, 102, 104–109, 112,  
114–116, 127–129,  
136–149, 158–159  
parietal branch of, 101–105  
posterior parietal branch of, 97  
posterior temporal branches of,  
97, 101, 102  
pre-central branches of, 97  
sylvian (insular) branches of,  
20–24, 99–100, 102–112,  
114–115, 117–119,  
122–137, 140–142,  
143–159  
temporo-occipital branch of,  
102
- Middle meningeal artery, 16–18,  
44, 52–55, 59–63, 66, 69,  
74  
cavernous branch of, 62  
frontal branch of, 17  
meningolacrimal branch of, 63  
parietal branch of, 17
- Muscular branches, 52–54, 56–57,  
66
- N**
- Nidus, 200, 202–207, 211–213
- Normal neurovascular anatomy  
frontal view of anterior  
(carotid) intracranial  
circulation, 21  
frontal view of head, neck,  
upper chest, 16  
frontal view of major cerebral  
veins and dural sinuses, 27  
lateral view of face, 17–18  
lateral view of posterior  
circulation, 23–24  
lateral view of posterior fossa  
veins, 28  
left anterior oblique view, 15  
medial view of right cerebral  
hemisphere, 19  
near lateral view supratentorial  
superficial and deep  
venous systems, 26  
oblique view of brain, 20  
posterior fossa veins seen from  
above, 29  
posterior fossa veins seen from  
dorsal aspect looking  
anteriorly, 30  
top down view of skull base, 22,  
25
- O**
- Occipital artery, 15, 49–55, 59–65,  
70–72, 74, 76–79
- Occipital sinus, 25–26, 28, 220,  
230–233
- Occipital veins, 243–247

- Occlusion of internal carotid artery, 62
- Ophthalmic artery, 19, 21–22, 90, 95, 97–100, 102–111, 113–120, 122–131, 134–153, 157–159
- P**
- Paired cavernous sinuses, 221
- Parietal veins, 243–247
- Pericallosal artery, 91–92
- Perimesencephalic veins, 67–69
- Petrosal vein, 28, 29, 67, 68, 243–247
- Pharyngeal artery, 18
- Pontine perforating artery, 19–20, 22–24, 170–175, 209–211
- Posterior auricular artery, 15, 49–55, 59–61, 64–65, 76
- Posterior cerebral artery, 136–137, 164–166, 168–169, 174–176, 183–185, 188–189, 196–215
- anterior temporal branches of, 19
- calcarine branch of, 23–24, 168–172, 174–180, 182–195, 200–211, 1920
- fetal origin of, 120
- mid-temporal branches of, 19–20
- P1 segment of, 19–20, 22–24, 170–172, 176–177, 180–182, 186–197, 209–211
- P2 segment of, 19–20, 22–24, 168–172, 174–182, 186–197, 200–211
- parieto-occipital branch of, 19–20, 22–24, 168–180, 183–195, 200–211
- posterior temporal branch of, 19–20, 20, 22–24, 23, 24, 168–169, 168–195, 170–172, 173, 176–177, 178–179, 180, 181, 182, 183–185, 200–211
- splenic branch of, 168–169, 180, 186–187, 188–189, 200–208
- Posterior choroidals, 178–179
- Posterior circulation, lateral view of, 23–24
- Posterior communicating artery, 19–20, 22–24, 77, 98, 102, 106–109, 113, 120–121, 124–129, 134–142, 145–149, 158–159, 164, 168–172, 178–180, 186–187, 190–195, 200–211
- infundibular widening at, 150–151
- origin of, 130–131
- stump of, 112
- Posterior draining group of posterior fossa veins, 225–226
- Posterior fossa veins
- lateral view of, 28
- seen from above, 29
- seen from dorsal aspect looking anteriorly, 30
- Posterior inferior cerebellar artery, 19–20, 22–24, 56, 84, 163, 168–211
- hemispheric branch of, 168–169, 174–175, 178–179, 186–189
- vermian branch of, 24, 168–169, 174–175, 178–179, 186–189
- Posterior intercavernous sinus, 25
- Posterior mesencephalic vein, 30, 243–247
- Posterior pericallosal artery, 19, 23, 24, 166–167, 180, 186–189, 200–208
- Posterior pericallosal vein, 26
- Posterior superior alveolar artery, 16, 18, 52–55, 66
- Posterior thalamoperforating arteries, 19–20, 20, 168–169, 174–175, 178–180, 186–189, 200–208, 212–215
- Precentral cerebellar vein, 28–30, 243–247
- Proximal meningohypophyseal trunk, 108–109
- Proximal middle cerebral artery branches, 95
- Proximal supraclinoid segment, 90
- Pterygoid canal artery, 18, 66
- Pterygoid venous plexus, 234–242, 254–257
- Pterygovaginal artery, 18

**Q**

Quadrigeminal plate cistern,  
168–169, 186–187,  
200–208

**R**

Radiculomedullary branches of  
vertebral arteries, 47  
Radiculomedullary feeder, 56, 86  
Recurrent artery of Heubner, 21,  
102, 106–107, 145  
Right common carotid artery,  
36–38, 40  
stump of, 15  
Right costocervical trunk, 15  
Right internal mammary artery,  
15, 36–37, 40  
Right subclavian artery, 15–16,  
36–40  
Right thyrocervical trunk, 15–16  
Right vertebral artery, 15, 36–37,  
39, 40

**S**

Second cervical vertebrae, 56, 57  
Septal vein, 26–27, 229–232,  
234–242, 249–257  
Sigmoid sinus, 25–29, 200–208,  
227–247, 249–257  
Skull base, top down view of, 22,  
25  
Sphenopalatine artery, 16, 18,  
52–55, 62–63, 66  
lateral nasal branches of, 52–55  
septal branches of, 52–55  
Sphenopalatine loop, 69

Sphenoparietal sinus, 25, 27, 221,  
230–232, 234–242  
Sphenopetrosal vein, 234–242  
Splenic artery, 19, 23, 24  
Stenosis, 59–61, 80–81, 84, 181,  
183–185  
Straight sinus, 25, 27–28, 30, 220,  
229–242, 246–247,  
254–257  
Suboccipital veins, 234–242,  
243–245, 254  
Superficial cerebral veins, 222  
Superficial cortical vein, 26–27,  
66, 222, 227–242,  
249–257  
Superficial middle cerebral vein,  
25–27, 66, 222, 230–232,  
234–242, 254–257  
Superficial temporal artery, 15, 43,  
49, 52–55, 62–66, 74, 76  
Superior cerebellar artery, 19–20,  
23–24, 164, 168–215  
hemispheric branch of, 23,  
168–189, 196–197,  
200–211  
vermian branch of, 24,  
170–187, 196–197,  
200–208  
Superior choroid vein, 28,  
246–247  
Superior draining group of  
posterior fossa veins,  
224–225  
Superior hypophyseal artery, 90  
Superior ophthalmic vein, 25, 66,  
234–242

Superior petrosal sinus, 25–27, 29,  
221, 229–232, 234–247,  
254–257  
Superior sagittal sinus, 25–27, 29,  
219, 227–245, 249–257  
Superior thalamic vein, 28,  
246–247  
Superior thyroid artery, 15–18,  
49–51, 55, 59–61, 64–65,  
70–73, 75–76  
Superior vermian vein, 28,  
246–247  
Supraclinoid segment of  
intracranial internal  
carotid artery, 90  
Surgical clipping, 116, 151  
Sylvian point, 21, 93, 95, 97,  
99–100, 106–111, 124–135,  
140–144, 150–157  
Sylvian triangle, 97  
Sylvian vein, 150–151

**T**

Temporal lobe, uncus of, 230–232  
Terminal vein, 26, 229, 234–242  
Thalamostriate vein, 26–27,  
229–232, 234–242,  
254–257  
Three-dimensional rotational  
angiography (3DRA)  
advantages of, 1–3  
for carotid artery disease in the  
neck, 45–46  
delay times, 9  
injection of contrast, 8–9  
limitations of, 3

- 
- reconstruction algorithms, 9–10  
techniques of, 7–10
- Tonsil, 191, 193, 195
- Torcular herophili, 25–29,  
227–247, 249–257
- Transverse facial artery, 15, 52–54
- Transverse pontine vein, 28–29
- Transverse sinus, 25–29, 220,  
227–247, 249–257
- True venous angle, 26, 234–242
- U**
- Ulcerated plaque, 70, 72–73, 76,  
183–185, 198–199
- Uncus of temporal lobe, 230–232
- Upper cervical segment dissection  
of vertebral artery, 85
- V**
- Vasculitis, 186–187
- Vein of Galen, 67–68
- Vein of Labbé, 25, 27, 227–232,  
234–242, 246–247, 249–257
- Vein of Trolard, 229–232, 234–242
- Venous angle, 223–224
- Vertebral artery, 19–20, 22–24,  
46–47, 56–57, 82–86,  
168–215
- Vertebral-basilar junction, 19–20,  
22–24, 168–169, 173,  
176–179, 186–187,  
190–211
- Vidian artery, 18, 66
